Epinephrine and norepinephrine are released by the adrenal medulla and nervous system respectively. They are the flight/fight hormones that are released when the body is under extreme stress. During stress, much of the body's energy is used to combat imminent danger. Kidney function is halted temporarily by epinephrine and norepinephrine. These hormones function by acting directly on the smooth muscles of blood vessels to constrict them. Once the afferent arterioles are constricted, blood flow into the nephrons stops. These hormones go one step further and trigger the **renin-angiotensin-aldosterone** system.

### Renin-Angiotensin-Aldosterone

The renin-angiotensin-aldosterone system, illustrated in **Figure 32.16** proceeds through several steps to produce **angiotensin II**, which acts to stabilize blood pressure and volume. Renin (secreted by a part of the juxtaglomerular complex) is produced by the granular cells of the afferent and efferent arterioles. Thus, the kidneys control blood pressure and volume directly. Renin acts on angiotensinogen, which is made in the liver and converts it to **angiotensin I**. **Angiotensin converting enzyme (ACE)** converts angiotensin I to angiotensin II. Angiotensin II raises blood pressure by constricting blood vessels. It also triggers the release of the mineralocorticoid aldosterone from the adrenal cortex, which in turn stimulates the renal tubules to reabsorb more sodium. Angiotensin II also triggers the release of **anti-diuretic hormone (ADH)** from the hypothalamus, leading to water retention in the kidneys. It acts directly on the nephrons and decreases glomerular filtration rate. Medically, blood pressure can be controlled by drugs that inhibit ACE (called ACE inhibitors).

**Figure 32.16** The renin-angiotensin-aldosterone system increases blood pressure and volume. The hormone ANP has antagonistic effects. (credit: modification of work by Mikael Häggström)

## Mineralocorticoids

Mineralocorticoids are hormones synthesized by the adrenal cortex that affect osmotic balance. Aldosterone is a mineralocorticoid that regulates sodium levels in the blood. Almost all of the sodium in the blood is reclaimed by the renal tubules under the influence of aldosterone. Because sodium is always reabsorbed by active transport and water follows sodium to maintain osmotic balance, aldosterone manages not only sodium levels but also the water levels in body fluids. In contrast, the aldosterone also stimulates potassium secretion concurrently with sodium reabsorption. In contrast, absence of aldosterone means that no sodium gets reabsorbed in the renal tubules and all of it gets excreted in the urine. In addition, the daily dietary potassium load is not secreted and the retention of  $\text{K}^+$  can cause a dangerous increase in plasma  $\text{K}^+$  concentration. Patients who have Addison's disease have a failing adrenal cortex and cannot produce aldosterone. They lose sodium in their urine constantly, and if the supply is not replenished, the consequences can be fatal.

## Antidiuretic Hormone

As previously discussed, antidiuretic hormone or ADH (also called **vasopressin**), as the name suggests, helps the body conserve water when body fluid volume, especially that of blood, is low. It is formed by the hypothalamus and is stored and released from the posterior pituitary. It acts by inserting aquaporins in the collecting ducts and promotes reabsorption of water. ADH also acts as a vasoconstrictor and increases blood pressure during hemorrhaging.

## Atrial Natriuretic Peptide Hormone

The atrial natriuretic peptide (ANP) lowers blood pressure by acting as a **vasodilator**. It is released by cells in the atrium of the heart in response to high blood pressure and in patients with sleep apnea. ANP affects salt release, and because water passively follows salt to maintain osmotic balance, it also has a diuretic effect. ANP also prevents sodium reabsorption by the renal tubules, decreasing water reabsorption (thus acting as a diuretic) and lowering blood pressure. Its actions suppress the actions of aldosterone, ADH, and renin.

### Think About It

Create a diagram to show an example of a hormone and how the hormone works in regulating an osmoregulatory process such as maintaining blood pressure and blood volume and altering kidney function to reduce the amount of water eliminated in urine.

## KEY TERMS

**afferent arteriole** arteriole that branches from the cortical radiate artery and enters the glomerulus

**ammonia** compound made of one nitrogen atom and three hydrogen atoms

**ammonotelic** describes an animal that excretes ammonia as the primary waste material

**angiotensin converting enzyme (ACE)** enzyme that converts angiotensin I to angiotensin II

**angiotensin I** product in the renin-angiotensin-aldosterone pathway

**angiotensin II** molecule that affects different organs to increase blood pressure

**anti-diuretic hormone (ADH)** hormone that prevents the loss of water

**antioxidant** agent that prevents cell destruction by reactive oxygen species

**arcuate artery** artery that branches from the interlobar artery and arches over the base of the renal pyramids

**ascending limb** part of the loop of Henle that ascends from the renal medulla to the renal cortex

**blood urea nitrogen (BUN)** estimate of urea in the blood and an indicator of kidney function

**Bowman's capsule** structure that encloses the glomerulus

**calyx** structure that connects the renal pelvis to the renal medulla

**cortex (animal)** outer layer of an organ like the kidney or adrenal gland

**cortical nephron** nephron that lies in the renal cortex

**cortical radiate artery** artery that radiates from the arcuate arteries into the renal cortex

**countercurrent exchanger** peritubular capillary network that allows exchange of solutes and water from the renal tubules

**countercurrent multiplier** osmotic gradient in the renal medulla that is responsible for concentration of urine

**descending limb** part of the loop of Henle that descends from the renal cortex into the renal medulla

**distal convoluted tubule (DCT)** part of the renal tubule that is the most distant from the glomerulus

**efferent arteriole** arteriole that exits from the glomerulus

**electrolyte** solute that breaks down into ions when dissolved in water

**flame cell** (also, protonephridia) excretory cell found in flatworms

**glomerular filtration** filtration of blood in the glomerular capillary network into the glomerulus

**glomerular filtration rate (GFR)** amount of filtrate formed by the glomerulus per minute

**glomerulus (renal)** part of the renal corpuscle that contains the capillary network

**hilum** region in the renal pelvis where blood vessels, nerves, and ureters bunch before entering or exiting the kidney

**inferior vena cava** one of the main veins in the human body

**interlobar artery** artery that branches from the segmental artery and travels in between the renal lobes

**juxtaglomerular cell** cell in the afferent and efferent arterioles that responds to stimuli from the macula densa

**juxtaglomerular nephron** nephron that lies in the cortex but close to the renal medulla

**kidney** organ that performs excretory and osmoregulatory functions

**lobes of the kidney** renal pyramid along with the adjoining cortical region

**loop of Henle** part of the renal tubule that loops into the renal medulla

**macula densa** group of cells that senses changes in sodium ion concentration; present in parts of the renal tubule and collecting ducts

**Malpighian tubule** excretory tubules found in arthropods

**medulla** middle layer of an organ like the kidney or adrenal gland

**microvilli** cellular processes that increase the surface area of cells

**molality** number of moles of solute per kilogram of solvent

**molarity** number of moles of solute per liter of solution

**mole** gram equivalent of the molecular weight of a substance

**nephridia** excretory structures found in annelids

**nephridiopore** pore found at the end of nephridia

**nephron** functional unit of the kidney

**non-electrolyte** solute that does not break down into ions when dissolved in water

**osmoconformer** organism that changes its tonicity based on its environment

**osmoregulation** mechanism by which water and solute concentrations are maintained at desired levels

**osmoregulator** organism that maintains its tonicity irrespective of its environment

**osmotic balance** balance of the amount of water and salt input and output to and from a biological system without disturbing the desired osmotic pressure and solute concentration in every compartment

**osmotic pressure** pressure exerted on a membrane to equalize solute concentration on either side

**perirenal fat capsule** fat layer that suspends the kidneys

**peritubular capillary network** capillary network that surrounds the renal tubule after the efferent artery exits the glomerulus

**proximal convoluted tubule (PCT)** part of the renal tubule that lies close to the glomerulus

**renal artery** branch of the artery that enters the kidney

**renal capsule** layer that encapsulates the kidneys

**renal column** area of the kidney through which the interlobar arteries travel in the process of supplying blood to the renal lobes

**renal corpuscle** glomerulus and the Bowman's capsule together

**renal fascia** connective tissue that supports the kidneys

**renal pelvis** region in the kidney where the calyces join the ureters

**renal pyramid** conical structure in the renal medulla

**renal tubule** tubule of the nephron that arises from the glomerulus

**renal vein** branch of a vein that exits the kidney and joins the inferior vena cava

**renin-angiotensin-aldosterone** biochemical pathway that activates angiotensin II, which increases blood pressure

**segmental artery** artery that branches from the renal artery

**semi-permeable membrane** membrane that allows only certain solutes to pass through

**transport maximum** maximum amount of solute that can be transported out of the renal tubules during reabsorption

**tubular reabsorption** reclamation of water and solutes that got filtered out in the glomerulus

**tubular secretion** process of secretion of wastes that do not get reabsorbed

**urea cycle** pathway by which ammonia is converted to urea

**ureotelic** describes animals that secrete urea as the primary nitrogenous waste material

**ureter** urine-bearing tube coming out of the kidney; carries urine to the bladder

**uric acid** byproduct of ammonia metabolism in birds, insects, and reptiles

**urinary bladder** structure that the ureters empty the urine into; stores urine

**urine** filtrate produced by kidneys that gets excreted out of the body

**vasa recta** peritubular network that surrounds the loop of Henle of the juxamedullary nephrons

**vasodilator** compound that increases the diameter of blood vessels

**vasopressin** another name for anti-diuretic hormone

## CHAPTER SUMMARY

### 32.1 Osmoregulation and Osmotic Balance

Solute concentrations across a semi-permeable membranes influence the movement of water and solutes across the membrane. It is the number of solute molecules and not the molecular size that is important in osmosis. Osmoregulation and osmotic balance are important bodily functions, resulting in water and salt balance. Not all solutes can pass through a semi-permeable membrane. Osmosis is the movement of water across the membrane. Osmosis occurs to equalize the number of solute molecules across a semi-permeable membrane by the movement of water to the side of higher solute concentration. Facilitated diffusion utilizes protein channels to move solute molecules from areas of higher to lower concentration while active transport mechanisms are required to move solutes against concentration gradients. Osmolarity is measured in units of milliequivalents or milliosmoles, both of which take into consideration the number of solute particles and the charge on them. Fish that live in fresh water or saltwater adapt by being osmoregulators or osmoconformers.

### 32.2 The Kidneys and Osmoregulatory Organs

The kidneys are the main osmoregulatory organs in mammalian systems; they function to filter blood and maintain the osmolarity of body fluids at 300 mOsm. They are surrounded by three layers and are made up internally of three distinct regions—the cortex, medulla, and pelvis.

The blood vessels that transport blood into and out of the kidneys arise from and merge with the aorta and inferior vena cava, respectively. The renal arteries branch out from the aorta and enter the kidney where they further divide into segmental, interlobar, arcuate, and cortical radiate arteries.

The nephron is the functional unit of the kidney, which actively filters blood and generates urine. The nephron is made up of the renal corpuscle and renal tubule. Cortical nephrons are found in the renal cortex, while juxamedullary nephrons are found in the renal cortex close to the renal medulla. The nephron filters and exchanges water and solutes with two sets of blood vessels and the tissue fluid in the kidneys.

There are three steps in the formation of urine: glomerular filtration, which occurs in the glomerulus; tubular reabsorption, which occurs in the renal tubules; and tubular secretion, which also occurs in the renal tubules.

### 32.3 Excretion Systems

Many systems have evolved for excreting wastes that are simpler than the kidney and urinary systems of vertebrate animals. The simplest system is that of contractile vacuoles present in microorganisms. Flame cells and nephridia in worms perform excretory functions and maintain osmotic balance. Some insects have evolved Malpighian tubules to excrete wastes and maintain osmotic balance.

### 32.4 Nitrogenous Wastes

Ammonia is the waste produced by metabolism of nitrogen-containing compounds like proteins and nucleic acids. While aquatic animals can easily excrete ammonia into their watery surroundings, terrestrial animals have evolved special mechanisms to eliminate the toxic ammonia from their systems. Urea is the major byproduct of ammonia metabolism in vertebrate animals. Uric acid is the major byproduct of ammonia metabolism in birds, terrestrial arthropods, and reptiles.

### 32.5 Hormonal Control of Osmoregulatory Functions

Hormonal cues help the kidneys synchronize the osmotic needs of the body. Hormones like epinephrine, norepinephrine, renin-angiotensin, aldosterone, anti-diuretic hormone, and atrial natriuretic peptide help regulate the needs of the body as well as the communication between the different organ systems.

## REVIEW QUESTIONS

- 1.** Why is the sodium ion at the highest concentration in extracellular fluid?
  - a. Sodium diffuses freely through the cell membrane.
  - b. The sodium/potassium pump removes sodium ions from the cell.
  - c. The blood contains a high concentration of sodium.
  - d. Sodium is actively taken up by the cells for use in the cytoplasm.
  
- 2.** What is given to a dehydrated human patient when he or she needs to be given fluids intravenously?
  - a. Water, which is hypotonic with respect to body fluids.
  - b. Saline at a concentration that is isotonic with respect to body fluids.
  - c. Glucose because it is a non-electrolyte.
  - d. blood
  
- 3.** What is the approximate osmolarity of body fluids?
  - a. 100 mOsm
  - b. 300 mOsm
  - c. 1000 mOsm
  - d. It is not constantly maintained.
  
- 4.** One milliequivalent of a ferric (III) ion ( $\text{Fe}^{+3}$ ) is equal to how many millimoles?
  - a. 0.13
  - b. 0.75
  - c. 0.5
  - d. 0.25
  
- 5.** What is the difference between an osmoregulator and an osmoconformer?
  - a. Osmoregulators can change the osmotic pressure of their body fluids, while osmoconformers cannot.
  - b. Osmoconformers can change the osmotic pressure of their body fluids, while osmoregulators cannot.
  - c. Osmoregulators match the osmotic pressure of their cells with that of the environment, while osmoconformers do not.
  - d. Osmoconformers match the osmotic pressure of their cells with that of the environment, while osmoregulators do not.
  
- 6.** Why does a salmon have to be an osmoregulator?
  - a. They need to remove excess salt from ocean water.
  - b. They move between areas of fresh and salt water.
  - c. They travel for short stretches across the land between streams.
  - d. Freshwater is osmotically neutral compared with their body fluids.
  
- 7.** What tends to happen to cells in a hypotonic environment?
  - a. They remain the same size.
  - b. They shrink due to water loss.
  - c. They allow water to flow in and out at the same rate.
  - d. They swell due to water gain.
  
- 8.** Which of the following is a function of the kidney?

- a. osmoregulation
  - b. excretion of solid waste
  - c. production of oxygen
  - d. reabsorption of all nutrients
- 9.** The kidney is made up of over a million nephrons that give it a granular appearance. What is a nephron?
- a. a network of capillaries
  - b. the cup-shaped chamber surrounding the glomerulus
  - c. the functional unit of the kidney
  - d. the bow-shaped artery at the base of medullary pyramids
- 10.** How do juxtamedullary nephrons differ from cortical nephrons?
- a. Juxtamedullary nephrons have a longer loop of Henle, allowing them to regulate urine concentration better than cortical nephrons.
  - b. Juxtamedullary nephrons have a shorter loop of Henle, allowing them to regulate urine concentration better than cortical nephrons.
  - c. Juxtamedullary nephrons have a larger glomerulus, allowing them to filter blood at a greater rate than cortical nephrons.
  - d. Juxtamedullary nephrons have a smaller glomerulus, allowing them to filter blood at a greater rate than cortical nephrons.
- 11.** What is the casing around the glomerulus called?
- a. distal tubule
  - b. loop of Henle
  - c. Bowman's capsule
  - d. renal pyramid
- 12.** In the loop of Henle, the permeability of the membrane changes. The descending limb and ascending limb are permeable to which of the following, respectively?
- a. solutes and water
  - b. proteins and solutes
  - c. water and proteins
  - d. water and solutes
- 13.** What do humans excrete, and how soluble is it compared to uric acid?
- a. urea, which is less soluble than uric acid
  - b. urea, which is more soluble than uric acid
  - c. ammonia, which is more soluble than uric acid
  - d. ammonia, which is less soluble than uric acid
- 14.** Describe the network of blood vessels of the kidney.
- a. Blood enters and exits the kidney at the renal hilum, and the renal blood supply starts with the branching of the aorta into the renal arteries. They end with the exiting of the renal veins to join the superior vena cava. Each segmental renal artery formed by the splitting of the renal arteries splits again into interlobar arteries and enters the renal columns. These again split to form arcuate arteries, from which cortical radiate arteries radiate out and branch into many afferent arterioles that enter the capillaries supplying the nephrons. Veins trace the path of arteries and have similar names, except there are no segmental veins.
  - b. Blood enters and exits the kidney at the renal hilum, and the renal blood supply starts with the branching of the aorta into the renal arteries. They end with the exiting of the renal veins to join the inferior vena cava. Each segmental renal artery formed by the splitting of the renal arteries splits again into interlobar arteries and enters the renal columns. These again split to form arcuate arteries, from which cortical radiate arteries radiate out and branch into many afferent arterioles that enter the capillaries supplying the nephrons. Veins trace the path of arteries and have similar names, except there are no segmental veins.
  - c. Blood enters and exits the kidney at the renal hilum, and the renal blood supply starts with the branching of the aorta into the renal arteries. They end with the exiting of the renal veins to join the inferior vena cava. Each segmental renal artery formed by the splitting of the renal arteries splits again into interlobar arteries and enters the renal columns. These again split to form cortical radiate arteries that radiate out and branch into many afferent arterioles that enter the capillaries supplying the nephrons. Veins trace the path of arteries and have similar names, except there are no segmental veins.
  - d. Blood enters and exits the kidney at the renal hilum, and the renal blood supply starts with the branching of the aorta into the renal arteries. They end with the exiting of the renal veins to join the inferior vena cava. Each segmental renal artery formed by the splitting of the renal arteries splits again into interlobar arteries and enters the renal columns. These again split to form arcuate arteries, from which cortical radiate arteries radiate out and branch into many afferent arterioles that enter the capillaries supplying the nephrons. Veins trace the path of arteries and have all the same names as the arteries following the same path.
- 15.** Which statement about contractile vacuoles in microorganisms is true?

- a. They exclusively perform an excretory function.  
 b. They contain digestive enzymes.  
 c. They originate from the cell membrane.  
 d. They are only used for fluid storage.
- 16.** Some unicellular organisms, such as the amoeba, ingest food by endocytosis. The food vesicle fuses with a lysosome, which digests the food. Waste is excreted by which process?
- exocytosis
  - filtration
  - osmoregulation
  - dilatation
- 17.** What does active transport of  $K^+$  in the Malpighian tubules ensure?
- Water leaves the Malpighian tubules.
  - Water moves into the Malpighian tubules.
  - $K^+$  moves into the Malpighian tubules.
  - $K^+$  leaves the Malpighian tubules.
- 18.** Flame cells are primitive excretory organs found in which organisms?
- arthropods
  - annelids
  - mammals
  - flatworms
- 19.** A cell has a malfunction in its contractile vacuoles. How would this affect the cell?
- The cell's nephrons would no longer be able to reabsorb water.
  - The cell's cytoplasm would become very concentrated.
  - The cell could no longer excrete waste products.
  - The cell would uncontrollably take on water until it burst.
- 20.** Which toxic substance is formed by nitrogenous waste?
- chlorine
  - potassium
  - ammonia
  - sodium
- 21.** What substance is secreted by most aquatic animals, and why?
- a. ammonia, because it can be easily diluted in an aquatic environment  
 b. uric acid, because aquatic animals must preserve water  
 c. urea, because ammonia needs to be converted before it can safely be stored in the body.  
 d. chlorine, because it can easily be converted to a gas
- 22.** Which water-insoluble compound is similar to purines found in nucleic acids and tends to form a white paste or powder?
- urea
  - guanine
  - ammonia
  - uric acid
- 23.** The urea cycle is also referred to as the \_\_\_\_\_ cycle.
- Krebs
  - ornithine
  - citric acid
  - uric acid
- 24.** Renin is produced in the kidney nephrons and performs what function?
- increases vasoconstriction
  - prevents loss of sodium
  - increases blood pressure
  - prevents water loss
- 25.** Which hormone elicits the “fight or flight” response, and under which circumstance is it released?
- anti-diuretic hormone, presence of alcohol in the blood
  - atrial natriuretic peptide, high blood pressure
  - aldosterone, low water content in the blood
  - epinephrine, extreme stress
- 26.** What are the cause and treatment of Addison’s disease?
- an excess of uric acid in the blood, uric acid-dissolving drugs
  - an inability to produce adh, drink excess water
  - an excess of  $K^+$  secretion into the urine, take in excess potassium
  - an inability to produce aldosterone, take in excess sodium
- 27.** How does atrial natriuretic peptide hormone act to lower blood pressure?

- a. vasoconstrictor
- b. vasodilator
- c. inhibitor
- d. vasopressin

28. Which cells or organs secrete renin?

## CRITICAL THINKING QUESTIONS

29. An organism is excreting ions in its urine. What is likely the current tonicity of the organism's cells, and why?

- a. hypotonicity due to too much solute in its body fluids
- b. hypertonicity due to less solute in its body fluids
- c. hypertonicity due to too much solute in its body fluids
- d. hypotonicity due to less solute in its body fluids

30. A student measures the osmolality of two aqueous solutions, A and B. The student finds that the osmolality of solution B is much higher than solution A. Based on this result, how do solutions A and B likely differ in the concentration of solutes in their solution, and why?

- a. Solution A likely is the more concentrated solution because osmolality measures the moles of solute per kilogram of solute.
- b. Solution B likely is the more concentrated solution because osmolality measures the moles of solute per kilogram of solvent.
- c. Solution A likely is the more concentrated solution because osmolality measures the moles of solute per kilogram of solvent.
- d. Solution B likely is the more concentrated solution because osmolality measures the moles of solute per kilogram of solute.

31. Would an organism that is constantly in a hypertonic environment likely be an osmoregulator or an osmoconformer? Why?

- a. osmoconformer, because it would need to prevent water from leaving its body to remain alive
- b. osmoregulator, because it would need to prevent solutes from leaving its body to remain alive
- c. osmoconformer, because it would need to prevent solutes from leaving its body to remain alive
- d. osmoregulator, because it would need to prevent water from leaving its body to remain alive.

32. Why is excretion important in order to achieve osmotic balance?

- a. granular cells of the juxtaglomerular apparatus
- b. the kidneys
- c. the nephrons
- d. water-reabsorbing cells of the collecting duct

a. The body accumulates water within itself when excretion does not occur, which can have dire consequences.

- b. Excretion regulates the movement of water within the membranes, which ultimately maintains osmotic balance.
- c. In the absence of excretion, there is a shift in the concentrations, which disrupts osmotic balance.
- d. The body builds up many chemical compounds that need to be excreted to maintain homeostasis and osmotic balance.

33. What is the structure of the nephron?

- a. The nephron consists of three parts: the glomerulus, the renal tubule, and the associated capillary network originating from the cortical radiate arteries.
- b. The nephron consists of three parts: the renal corpuscle, the Bowman's capsule, and the associated capillary network originating from the cortical radiate arteries.
- c. The nephron consists of three parts: the renal corpuscle, the renal tubule, and the associated capillary network originating from the segmental renal artery.
- d. The nephron consists of three parts: the renal corpuscle, the renal tubule, and the associated capillary network originating from the cortical radiate arteries.

34. How does the loop of Henle act as a countercurrent multiplier?

- a. The descending limb of the loop of Henle is water permeable, so the water flows from the filtrate to the interstitial fluid. Osmolality in the limb decreases, and it is lower inside the loop than in the interstitial fluid. As the filtrate enters the ascending limb,  $\text{Na}^+$  and  $\text{Cl}^-$  ions exit through ion channels present in the cell membrane. Further up, only sodium is passively transported out of the filtrate.
- b. The descending limb of the loop of Henle is water impermeable, so the water flows from the filtrate to the interstitial fluid. Osmolality in the limb increases, and it is higher inside the loop than in the interstitial fluid. As the filtrate enters the ascending limb,  $\text{Na}^+$  and  $\text{Cl}^-$  ions exit through ion channels present in the cell membrane. Further up, only sodium is passively transported out of the filtrate.
- c. The descending limb of the loop of Henle is water impermeable, so the water flows from the filtrate to the interstitial fluid. Osmolality in the limb increases, and it is higher inside the loop than in the interstitial fluid. As the filtrate enters the ascending limb,  $\text{Na}^+$  and  $\text{Cl}^-$  ions exit through ion channels present in the cell membrane. Further up, sodium is actively transported out of the filtrate, and chlorine ions follow.
- d. The descending limb of the loop of Henle is water permeable, so the water flows from the filtrate to the interstitial fluid. Osmolality in the limb increases, and it is higher inside the loop than in the interstitial fluid. As the filtrate enters the ascending limb,  $\text{Na}^+$  and  $\text{Cl}^-$  ions exit through ion channels present in the cell membrane. Further up, sodium is actively transported out of the filtrate, and chlorine ions follows.

**35.** Why might specialized organs have evolved for excretion of wastes?

- a. Specialized organs have evolved to provide a measure of safety for organisms.
- b. Specialized organs have evolved to distinguish different types of organisms.
- c. Specialized organs have evolved for excretion of wastes to conserve metabolic energy.
- d. Specialized organs have evolved for excretion of wastes so that organisms can survive in adverse conditions.

**36.** Explain two different excretory systems other than the kidneys.

- a. (1) An excretory mechanism occurs in annelids through the Malpighian tubules. Metabolic wastes like uric acid freely diffuse into the tubules. Uric acid is excreted as a thick paste or powder. (2) An excretory mechanism occurs in the flatworm, which contains two tubules with cells called flame cells. They have cilia that propel waste matter down the tubules and out of the body.
- b. (1) An excretory mechanism occurs in arthropods through a pore called the nephridiopore. These organisms have a system for tubular reabsorption. (2) An excretory mechanism occurs in annelids through the Malpighian tubules. Metabolic wastes like uric acid freely diffuse into the tubules. Uric acid is excreted as a thick paste or powder.
- c. (1) An excretory mechanism is endocytosis, which occurs when vacuoles merge with the cell membrane and excrete cellular wastes in the environment. (2) An excretory mechanism occurs in annelids through a pore called the nephridiopore. These organisms have a system for tubular reabsorption.
- d. (1) An excretory mechanism is exocytosis, which occurs when vacuoles merge with the cell membrane and excrete cellular wastes in the environment. (2) An excretory mechanism occurs in flatworms which consists of two tubules containing cells called flame cells. They have a cluster of cilia that propel waste matter down the tubules and out of the body.

**37.** How do contractile vacuoles work as excretory systems in microorganisms?

- a. Contractile vacuoles excrete excess water and waste by the process of endocytosis, in which these vacuoles merge with cell membrane and expel wastes into the environment.
- b. Contractile vacuoles excrete uric acid by the process of exocytosis, in which water as well as uric acid is excreted by contraction of a cell when the vacuole merges with the cell membrane.
- c. Contractile vacuoles excrete excess water and uric acid by the process of endocytosis when the vacuole merges with the cell membrane.
- d. Contractile vacuoles excrete excess water and waste by the process of exocytosis, in which the vacuoles merge with the cell membrane and expel wastes into the environment.

**38.** Describe the urea cycle.

- a. The urea cycle is the mechanism of conversion of urea to ammonia involving five intermediate steps catalyzed by five different enzymes. Of the five steps, the first two occur in the mitochondria and the last three in the cytosol.
- b. The urea cycle is the mechanism of conversion of ammonia to urea involving five intermediate steps catalyzed by five different enzymes. Of the five steps, the first two occur in the mitochondria and the last three in the cytosol.
- c. The urea cycle is the mechanism of conversion of ammonia to urea involving five intermediate steps catalyzed by five different enzymes. Of the five steps, the first two occur in the cytosol and the last three in the mitochondria.
- d. The urea cycle is the mechanism of conversion of ammonia to urea involving five intermediate steps all catalyzed by one enzyme. Of the five steps, the first two occur in the mitochondria and the last three in the cytosol.

**39.** How are the formation of urea and uric acid similar and different?

- a. In birds, reptiles, and insects, the urea cycle converts ammonia to urea. In mammals, the uric acid cycle converts ammonia to uric acid. Formation of urea from ammonia requires less energy and is less complex than uric acid formation.
- b. In mammals, the urea cycle converts ammonia to urea. In birds, reptiles, and insects, the uric acid cycle converts ammonia to uric acid. Formation of urea from ammonia requires more energy and is less complex than uric acid formation.
- c. In mammals, the urea cycle converts ammonia to urea. In birds, reptiles, and insects, the uric acid cycle converts ammonia to uric acid. Formation of urea from ammonia requires less energy and is more complex than uric acid formation.
- d. In mammals, the urea cycle converts ammonia to urea. In birds, reptiles, and insects, the uric acid cycle converts ammonia to uric acid. Formation of urea from ammonia requires less energy and is less complex than uric acid formation.

**40.** In terms of evolution, why might the urea cycle have evolved in organisms?

- a. so organisms could adapt to the changing environment when terrestrial life forms evolved
- b. so organisms could evolve the ability to switch between direct ammonia excretion and urea
- c. so organisms could reduce their excretion of ammonia in the form of urea
- d. so organisms could adapt to the changing environment and excrete higher concentrations of uric acid

**41.** How do hormones regulate blood pressure, blood volume, and kidney function?

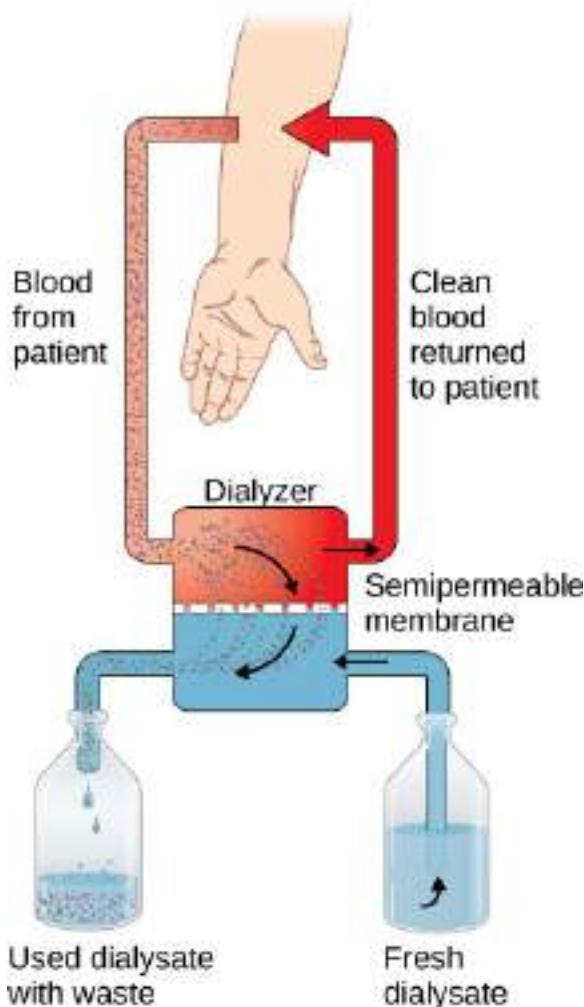

- a. Different regions of the liver have specialized cells that respond to chemical messengers and hormones like epinephrine, renin, aldosterone, ADH, and ANP. These regulate the needs of the body and communication between different organ systems.
- b. Different regions of the nephrons have specialized cells that respond to chemical messengers and hormones like epinephrine, renin, aldosterone, ADH, and ANP. These regulate the rate of respiration and communication between the different organ systems.
- c. Different regions of the kidneys have specialized cells that respond to chemical messengers and hormones like epinephrine, renin, aldosterone, ADH, and ANP. These regulate the rate of respiration and communication between the different organ systems.
- d. Different regions of the nephrons have specialized cells that respond to chemical messengers and hormones like epinephrine, renin, aldosterone, ADH, and ANP. These regulate the needs of the body and communication between the different organ systems.

**42.** How does the renin-angiotensin-aldosterone mechanism function?

- a. Renin, which is secreted by part of the juxtaglomerular complex, acts on angiotensin to form angiotensin I, which is then converted to angiotensin II by ACE. Angiotensin II then stimulates the release of aldosterone and ADH. Angiotensin II acts to destabilize blood pressure and volume.
- b. Renin, which is secreted by part of the juxtaglomerular complex, acts on angiotensin to form angiotensin II, which is then converted to angiotensin I by ACE. Angiotensin II then stimulates the release of aldosterone and ADH. Angiotensin II acts to stabilize blood pressure and volume.
- c. Renin, which is secreted by part of the juxtaglomerular complex, acts on angiotensin to form angiotensin I, which is then converted to angiotensin II and ADH by ACE. ADH then stimulates the release of aldosterone. Angiotensin II acts to stabilize blood pressure and volume.
- d. Renin, which is secreted by part of the juxtaglomerular complex, acts on angiotensin to form angiotensin I, which is then converted to angiotensin II by ACE. Angiotensin II then stimulates the release of aldosterone and ADH. Angiotensin II acts to stabilize blood pressure and volume.
- 43. What is the “fight or flight” response, and what is its effect on the excretory system?**
- a. Aldosterone is the “fight or flight” that is released by the adrenal medulla under extreme stress. This hormone constricts the smooth muscles of the blood vessels. It constricts the afferent arterioles, causing the flow of blood into the nephrons to stop.
- b. Epinephrine and norepinephrine are the “fight or flight” hormones that are released by the adrenal medulla and the nervous system, respectively, under extreme stress. These hormones constrict the smooth muscles of the blood vessels. They constrict the afferent arterioles, causing the flow of blood into the nephrons to stop.
- c. ADH is the “fight or flight” hormone that is released by the adrenal medulla under extreme stress. This hormone constricts the smooth muscles of the blood vessels. It constricts the efferent arterioles, causing the flow of blood into the nephrons to stop.
- d. Epinephrine and norepinephrine are the “fight or flight” hormones that are released by the adrenal medulla and the nervous system, respectively, under extreme stress. These hormones constrict the smooth muscles of the blood vessels. They constrict the efferent arterioles, causing the flow of blood into the nephrons to stop.

## TEST PREP FOR AP® COURSES

**44.**

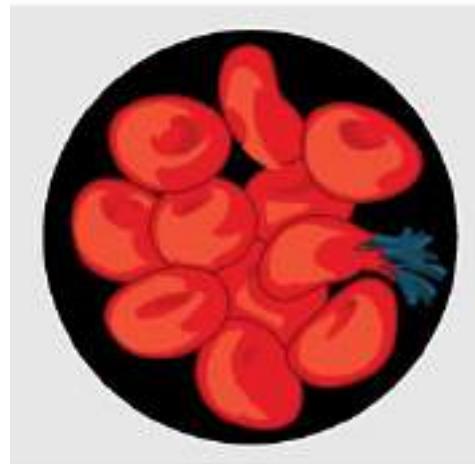

Patients with kidney illnesses use dialysis machines to remove harmful urea from their blood. The blood is separated from a solution, called the dialysate, that is designed to remove wastes by diffusion through a semipermeable membrane. How does the concentration of solutes likely differ between the upper component of the dialyzer and the lower compartment, containing the fresh dialysate, for the dialysis to successfully remove wastes from the blood?

- In the upper component, the dialysate has a higher solute concentration than the blood, which allows the urea to diffuse to the lower dialysate down its concentration gradient.
- In the upper component, the dialysate has a lower solute concentration than the blood, which allows the urea to be separated via active transport down the concentration gradient.
- In the upper component, the dialysate has a higher solute concentration than the blood, which allows the urea to utilize facilitated diffusion in order to diffuse to the lower dialysate.
- In the upper component, the dialysate has a lower solute concentration than the blood, which allows the urea to diffuse to the lower dialysate down its concentration gradient.

45.

Solution A

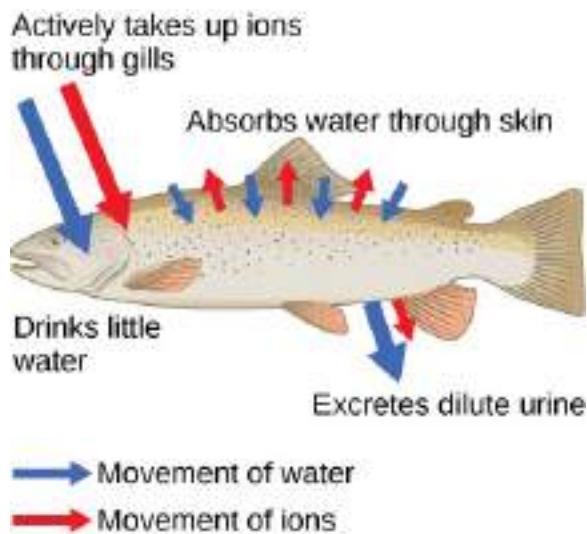

Solution B

The diagram shows red blood cells in two different NaCl solutions. What is likely causing the cells to differ in shape in the two solutions?

- Solution A has high osmolarity. Solution B has low osmolarity.
- Solution A has low osmolarity. Solution B high osmolarity.
- The cells in solution A are osmoregulators. The cells in solution B are osmoconformers.
- The cells in solution A are osmoconformers. The cells in solution B are osmoregulators.

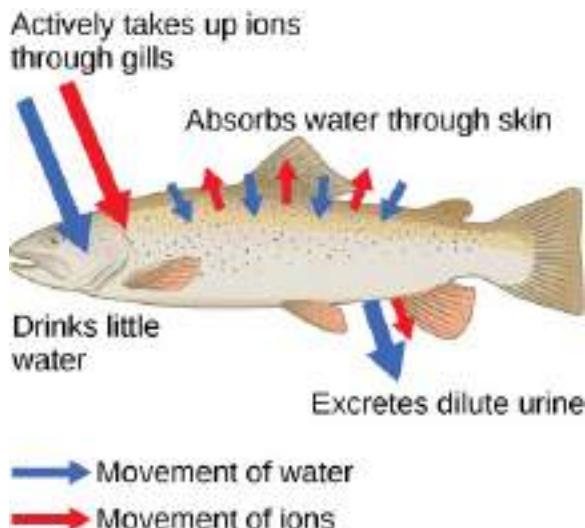

46.

This diagram models the osmotic pressures experienced by a fish. Based on the direction of water and solute movements shown in the diagram, is this fish likely a saltwater or freshwater fish? How do you know?

- freshwater, because the fish is osmoregulating in response to a hypertonic solution
- freshwater, because the fish is osmoregulating in response to a hypotonic solution
- saltwater, because the fish is osmoregulating in response to a hypertonic solution
- saltwater, because the fish is osmoregulating in response to a hypotonic solution

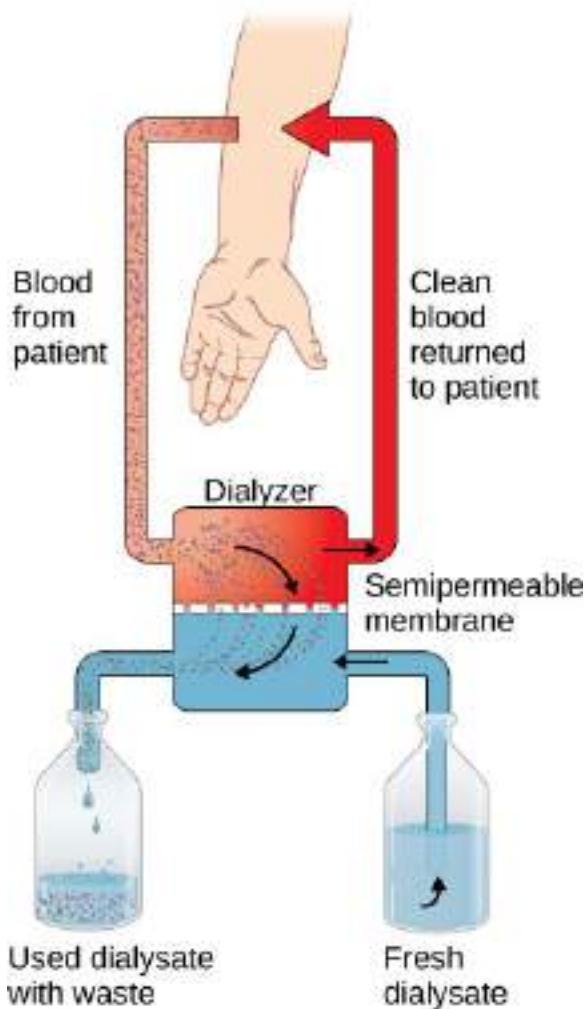

47.

The diagram models the osmotic pressures experienced by a fish. Why would this fish most likely drink little water but excrete dilute urine? Explain your answer in terms of the osmolarity of the water it lives in.

- The high osmolarity of the water would cause accumulation of too many salts in the body of the fish.
- The water it lives in has very low osmolarity, which causes water to constantly diffuse into the fish's body.
- The water it lives in has very high osmolarity, which causes water to constantly diffuse out of the fish's body.
- The water it lives in has very high osmolarity, which causes water to constantly diffuse into the fish's body.

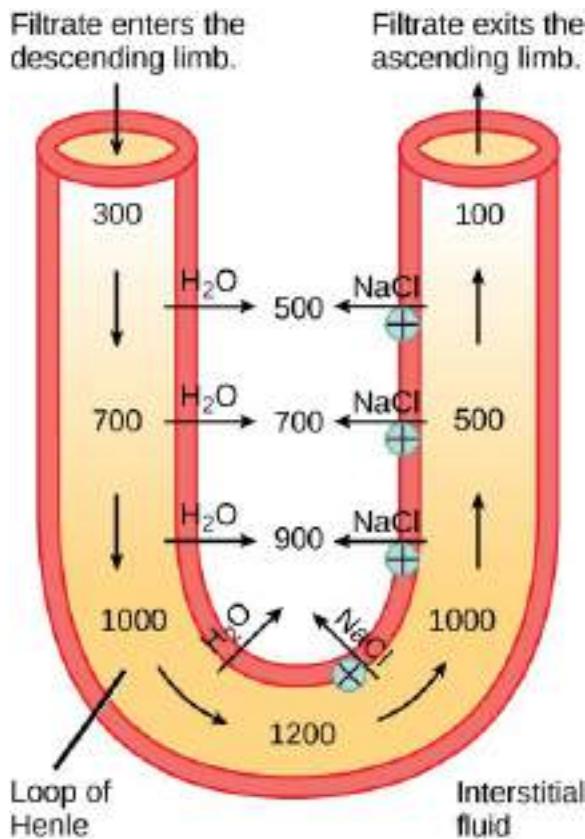

48.

Patients with kidney illnesses use dialysis machines to remove harmful urea from their blood. The blood is separated from a solution, called the dialysate, that is designed to remove wastes by diffusion through a semipermeable membrane. The semipermeable membrane is likely permeable to \_\_\_\_\_ and impermeable to \_\_\_\_\_.

- red blood cells, urea
- dialysate, blood plasma
- blood plasma, urea
- urea, red blood cells

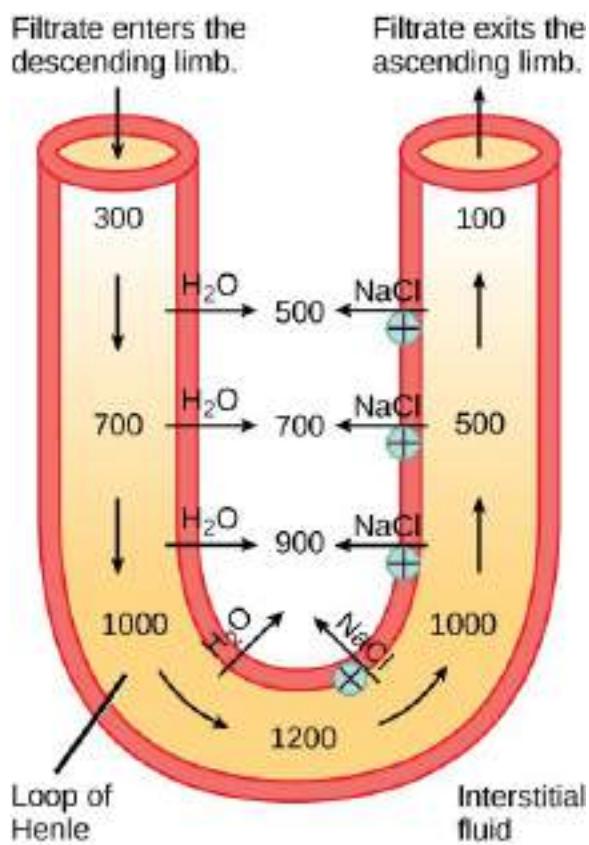

49.

The diagram models the countercurrent exchange mechanism within the loop of Henle. The numbers within the loop show the osmolarity of the filtrate, while the numbers between the two loops indicate the osmolarity of the interstitial fluid within the kidney tissue. What would likely occur to the osmolarity of the filtrate in the ascending limb if the active transport of NaCl stopped?

- Filtrate osmolarity would increase, then decrease.
- Filtrate osmolarity would stay the same.
- Filtrate osmolarity would decrease.
- Filtrate osmolarity would increase.

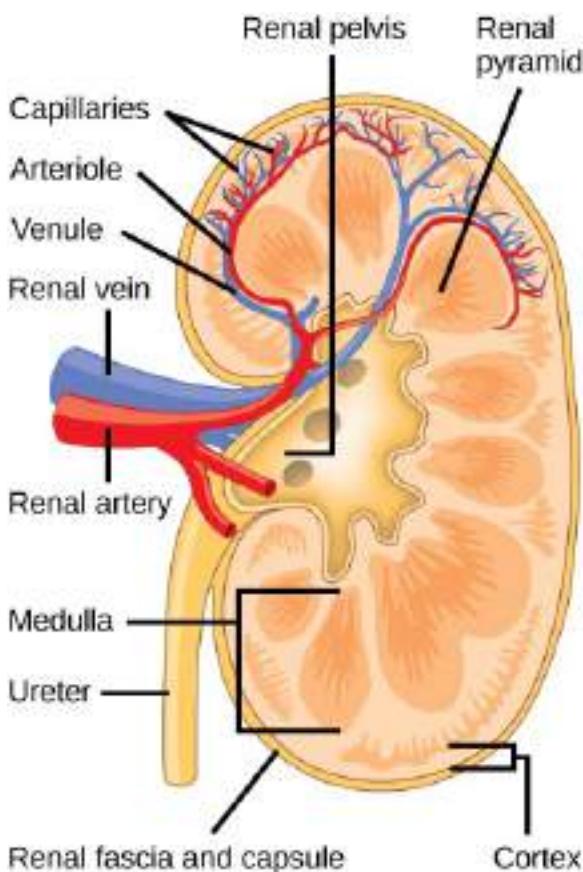

50.

The diagram models the countercurrent exchange mechanism within the loop of Henle. The numbers within the loop show the osmolarity of the filtrate, while the numbers between the two loops indicate the osmolarity of the interstitial fluid within the kidney tissue. What would happen to the osmolarity of the interstitial fluid if water could not exit the descending limb?

- Osmolarity of the interstitial fluid would increase.
- Osmolarity of the interstitial fluid would decrease.
- There would be no change in the osmolarity.
- Osmolarity would increase or decrease depending upon the amount of water.

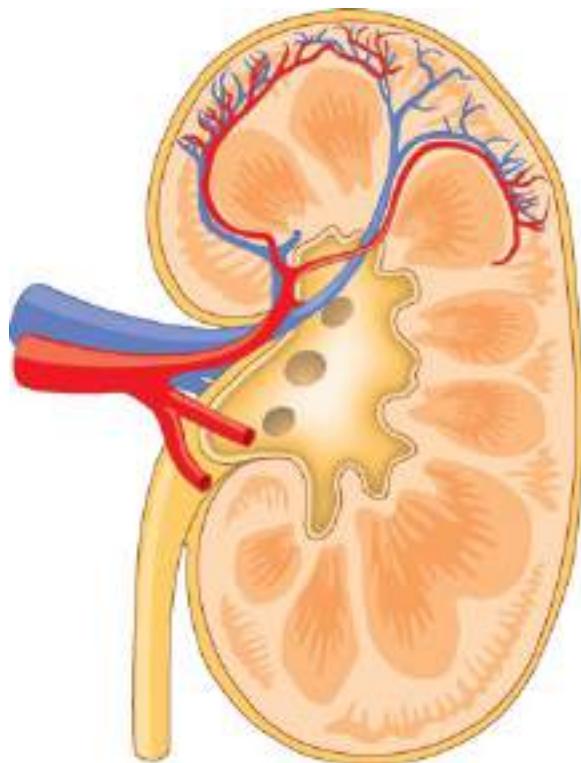

51.

The diagram shows a cross-section of a kidney. What would likely occur if there was a blood clot in the renal artery?

- Filtration in the glomerulus would decrease.
- Fluid levels in the renal pelvis would increase.
- Blood would not drain into the convoluted tubule.
- Urea production would increase.

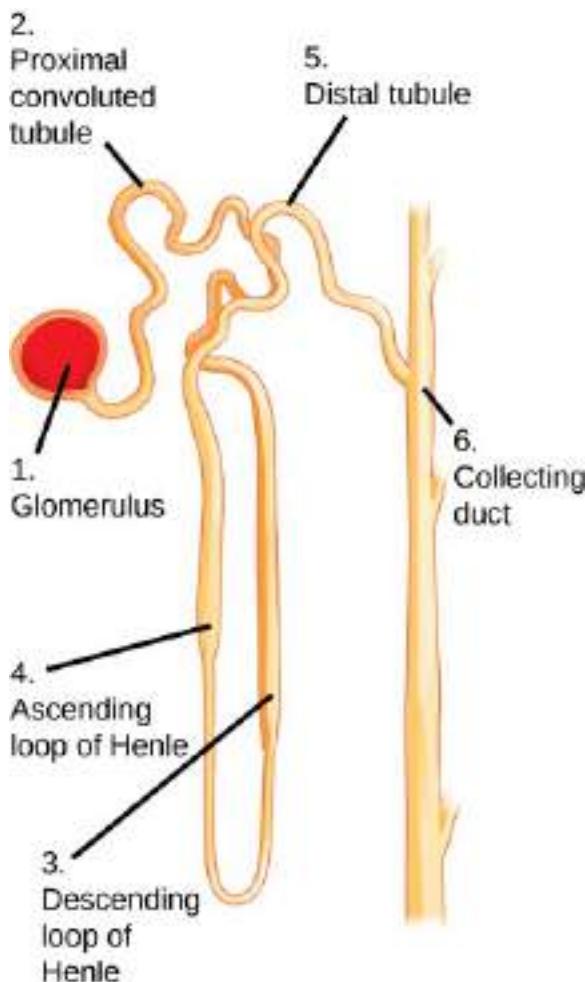

52.

The diagram shows the left kidney. Why do the capillaries carrying blood from the renal artery run over the top of the renal pyramids?

- The capillaries deliver blood to the glomerulus and run parallel to the proximal convoluted tubule. Both are located in the medulla.
- The capillaries deliver blood to the glomerulus and run perpendicular to the proximal convoluted tubule. Both are located in the cortex.
- The capillaries deliver blood to the glomerulus and run perpendicular to the distal convoluted tubule. Both are located in the cortex.
- The capillaries deliver blood to the glomerulus and run parallel to the distal convoluted tubule. Both are located in the cortex.

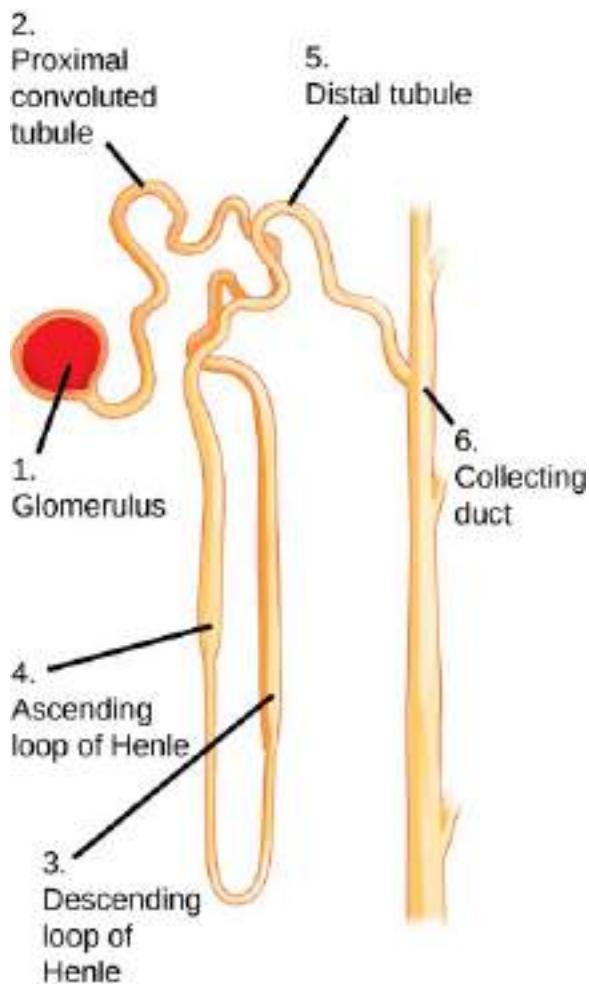

53.

The figure shows the components of a nephron located within the kidneys. What would likely occur in the collecting duct if there was increased blood flow to the glomerulus?

- More water would enter the collecting duct.
- More urea would enter the collecting duct.
- Less NaCl would leave the collecting duct.
- Less urea would leave the collecting duct.

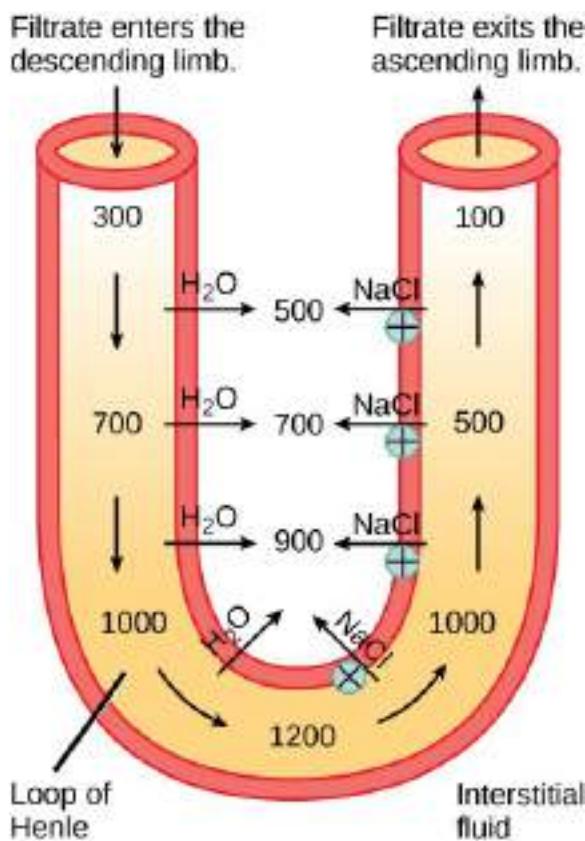

54.

The figure below shows the components of a nephron located within the kidneys. Alcohol impairs the pituitary gland, which controls how much water is reabsorbed by the nephrons. The hormone produced by the pituitary gland, anti-diuretic hormone, increases water reabsorption by the kidney. How would impairment of this hormone likely affect the various components of the nephron pictured below?

- Absorption of water from the filtrate would decrease, indicated by decreased loss of water in the descending loop of Henle, increased solute secretion into the distal tubule, and decreased water absorbtion in the collecting duct.
- Absorption of water from the filtrate would decrease, indicated by decreased loss of water in the ascending loop of Henle, increased solute secretion into the distal tubule, and increased water absorption in the collecting duct.
- Absorption of water from the filtrate would decrease, indicated by decreased loss of water in the ascending loop of Henle, increased solute secretion into the distal tubule, and decreased water absorbtion in the collecting duct.
- Absorption of water from the filtrate would decrease, indicated by decreased loss of water in the descending loop of Henle, increased solute secretion into the distal tubule, and increased water absorption in the collecting duct.

55.

The diagram models the countercurrent exchange mechanism within the loop of Henle. The numbers within the loop show the osmolarity of the filtrate, while the numbers between the two loops indicate the osmolarity of the interstitial fluid within the kidney tissue. What would likely happen to the osmolarity of the filtrate in the ascending limb if the body released urea into the

interstitial fluid?

- a. The osmolarity would decrease, allowing the interstitial fluid to reabsorb solutes.
- b. The osmolarity would decrease, allowing the interstitial fluid to reabsorb water.
- c. The osmolarity would increase, allowing the interstitial fluid to reabsorb solutes.
- d. The osmolarity would increase, allowing the interstitial fluid to reabsorb water.

**56.** Planaria are flatworms that live in fresh water. Their excretory system, or protonephridia, consists of two tubules connected to a highly branched tube system. The intake end of the tubes contain cilia that propel waste matter down the tubules and out of the body through excretory pores that open on the body surface. Cilia also draw water from the interstitial fluid, allowing for filtration. Any valuable metabolites are recovered by reabsorption. What structure in the human kidneys most closely resembles the cilia of the protonephridia, and why?

- a. The renal artery, because it facilitates the exchange of nutrients with the blood
- b. The convoluted tubule, because it facilitates the exchange of nutrients with the blood
- c. The glomerulus, because it facilitates filtering of the blood
- d. The ureter, because it facilitates filtering of the blood

**57.** Planaria are flatworms that live in fresh water. Their excretory system, or protonephridia, consists of two tubules connected to a highly branched tube system. The intake end of the tubes contain cilia that propel waste matter down the tubules and out of the body through excretory pores that open on the body surface. Cilia also draw water from the interstitial fluid, allowing for filtration. Any valuable metabolites are recovered by reabsorption. What structure in the human kidneys most closely resembles the highly branched tube system of the protonephridia, and why?

- c. The glomerulus, because it facilitates filtering of the blood
- d. The ureter, because it facilitates filtering of the blood

**58.** Planaria are flatworms that live in fresh water. Their excretory system, or protonephridia, consists of two tubules connected to a highly branched tube system. The intake end of the tubes contain cilia that propel waste matter down the tubules and out of the body through excretory pores that open on the body surface. Cilia also

draw water from the interstitial fluid, allowing for filtration. Any valuable metabolites are recovered by reabsorption. What structure in the human kidneys most closely resembles the excretory pores of the protonephridia, and why?

- a. The urethral opening, because this is where wastes leave the body
- b. The convoluted tubule, because this is where reabsorption and secretion occur
- c. The glomerulus, because this is where reabsorption and secretion occur
- d. The ureter, because this is where wastes leave the body.

**59.** The Malpighian tubules filter waste materials out of the blood, or hemolymph, of insects. There are cells lining the tubules that pump solutes (mainly ions) into the space surrounding the Malpighian tubules. If you observed a gradual increase in the solute concentration outside of the Malpighian tubules, what would you expect to happen?

- a. Water would be drawn out of the hemolymph within the tubule.
- b. Water would be drawn into the tubule.
- c. Ions would be drawn out of the hemolymph within the tubule.
- d. Ions would be drawn into the tubule.

**60.** The flame cells of a protonephridia filter waste materials out of the blood, or hemolymph, of invertebrates. What would this be most similar to, in function, in the human excretory system?

- a. the ascending loop of henle
- b. the descending loop of henle
- c. the distal convoluted tubule
- d. Bowman's capsule

**61.** Terrestrial arthropods, birds, and reptiles convert toxic ammonia to uric acid or the closely related compound guanine (guano). However, the conversion of ammonia to uric acid requires more energy and is much more complex than the conversion of ammonia to urea, or the excretion of ammonia as performed by fish. Based on these findings, how may the excretory system of one of the terrestrial organisms listed above change if it evolved to spend most of its time in water?

- a. They may evolve the ability to switch between uric acid and direct ammonia excretion.
- b. They would further reduce their excretion of ammonia.
- c. They may evolve the ability to excrete uric acid without having to dissolve it in any water.
- d. They would excrete higher concentrations of uric acid.

**62.** Birds and reptiles convert toxic ammonia to uric acid

or the closely related compound guanine (guano), reflecting the close evolutionary ancestry of these groups. However, terrestrial arthropods also convert ammonia to uric acid. This is as opposed to fish, which excrete ammonia directly, without converting it to another substance. However, the conversion of ammonia to uric acid requires more energy and is much more complex than the conversion of ammonia to urea. What do these findings suggest about why these organisms evolved the conversion of ammonia to uric acid?

- To evolve the ability to switch between uric acid and ammonia excretion
- To conserve water to allow them to persist on land
- For reduction in excretion of ammonia
- For excretion of higher concentrations of ammonia

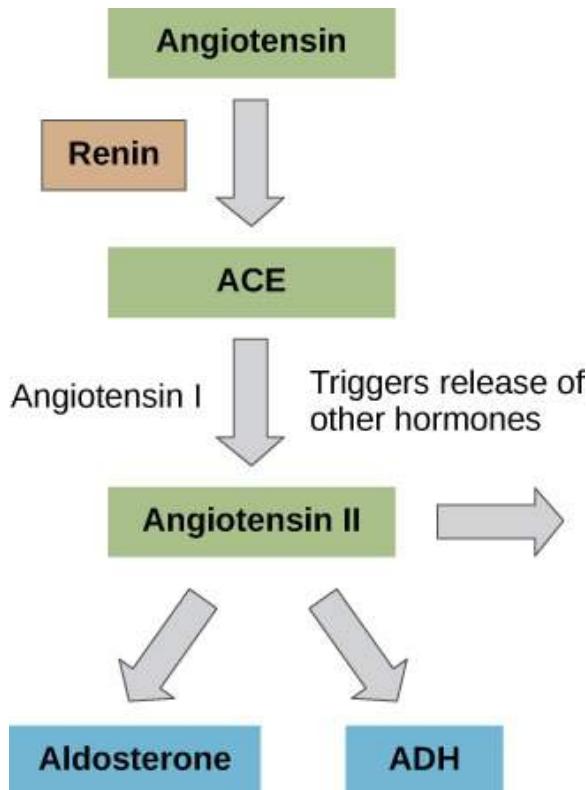

**63.** The kidneys are controlled by hormones from the brain, liver, and other locations. However, the kidneys also produce the hormone renin in their juxtaglomerular complex. How would damage to the juxtaglomerular complex affect the renin-angiotensin-aldosterone system?

- Aldosterone will not be produced, decreasing blood volume
- Angiotensin I will not be produced, decreasing blood pressure
- Angiotensin-converting enzyme will not be produced, increasing sodium reabsorption.
- Angiotensin II will not be produced, increasing the glomerular filtration rate.

**64.** The atrial natriuretic peptide (ANP) lowers blood pressure by acting as a vasodilator. It is released by cells in the atrium of the heart in response to high blood pressure and in patients with sleep apnea. ANP prevents sodium reabsorption by the renal tubules. Therefore, what excretory system symptom might someone with sleep apnea also experience and why?

- reduction in urination due to reduction of water reabsorption in the kidneys
- excessive sodium reabsorption by renal tubes due to increase in water reabsorption in the kidneys
- excessive sodium reabsorption by renal tubes due to reduction of water reabsorption in the kidneys
- excessive urination due to reduction of water reabsorption in the kidneys

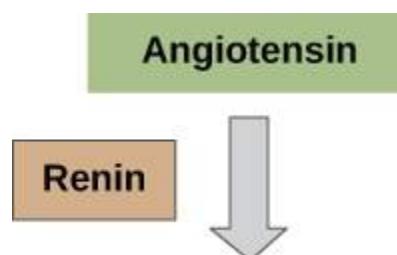

**65.**

This diagram was made by a student to illustrate the angiotensin-aldosterone system. What part of this diagram contains an error?

- ADH is not produced in this system.
- The diagram is missing ANP.
- ACE and renin should be switched.
- ACE and angiotensin should be switched.

**66.**

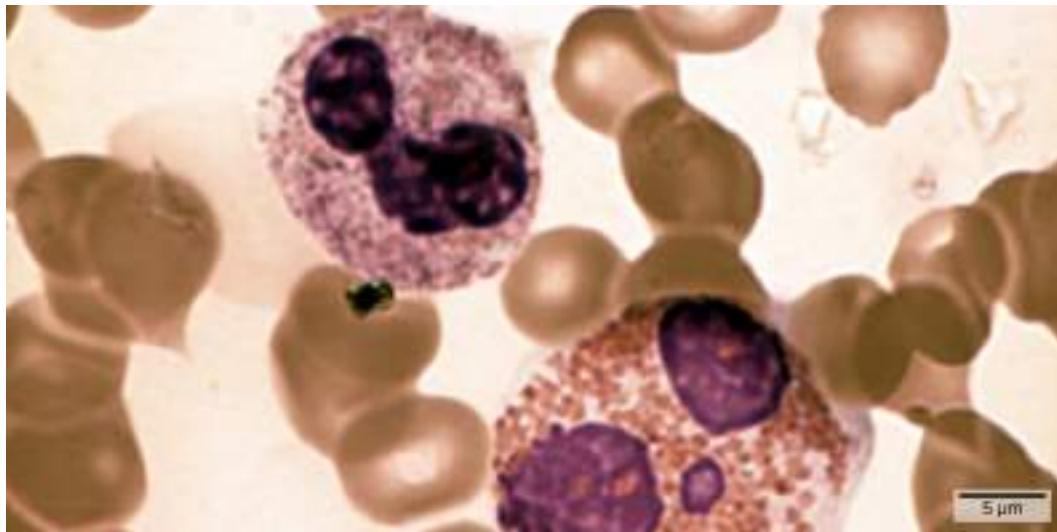

This diagram was made by a student to illustrate the angiotensin-aldosterone system. How would you complete this diagram to make it an accurate model of the renin-angiotensin system?

- a. Renin acts on angiotensin to directly stimulate the release of aldosterone and ADH.
- b. Renin acts on angiotensin to form ACE and angiotensin II, which then stimulates the release of aldosterone and ADH.
- c. Angiotensin II is formed from angiotensin, which is then converted to angiotensin I by ACE. Aldosterone and ADH are then stimulated to be released from angiotensin I.
- d. Angiotensin I is formed from angiotensin, which is then converted to angiotensin II by ACE. Aldosterone and ADH are then stimulated to be released from angiotensin II.

# 33 | THE IMMUNE SYSTEM

**Figure 33.1** In this compound light micrograph purple-stained neutrophil (upper left) and eosinophil (lower right) are white blood cells that float among red blood cells in this blood smear. Neutrophils provide an early, rapid, and nonspecific defense against invading pathogens. Eosinophils play a variety of roles in the immune response. Red blood cells are about 7–8  $\mu\text{m}$  in diameter, and a neutrophil is about 10–12  $\mu\text{m}$ . (credit: modification of work by Dr. David Csaba)

## Chapter Outline

- 33.1: Innate Immune Response**
- 33.2: Adaptive Immune Response**
- 33.3: Antibodies**
- 33.4: Disruptions in the Immune System**

## Introduction

The environment consists of numerous **pathogens**, which are agents, usually microorganisms, that cause diseases in their hosts. A **host** is the organism that is invaded and often harmed by a pathogen. Pathogens include bacteria, protists, fungi and other infectious organisms. We are constantly exposed to pathogens in food and water, on surfaces, and in the air. Mammalian immune systems evolved for protection from such pathogens; they are composed of an extremely diverse array of specialized cells and soluble molecules that coordinate a rapid and flexible defense system capable of providing protection from a majority of these disease agents.

Vaccines were developed to reduce the chance of infection of a particular disease, such as measles, mumps, polio, or chicken pox, by assisting the body to develop immunity. However, many diseases still do not have a vaccine, such as the deadly disease caused by the Ebola virus. Data from the World Health Organization indicates that more than 11,000 people died out of over 27,000 cases reported during the 2014–2015 outbreak. Though the majority of the cases were in Africa, Ebola did spread to other countries and prompted researchers to try to find a treatment. You can read more about this research at the **Science Daily website** (<http://openstaxcollege.org/l/32ebolavirus>) .

## 33.1 | Innate Immune Response

In this section, you will explore the following questions:

- What are examples of physical and chemical immune barriers?
- What are the immediate and induced immune responses?
- What are natural killer cells, and what is their role in immunity?
- What are the features of histocompatibility class I molecules?
- How do the proteins in a complement system function to destroy extracellular pathogens?

### Connection for AP® Courses

Much of the information about the different organ systems of vertebrate animals is not within the scope for AP®. The immune system, however, was chosen for in-depth exploration because all organisms, including humans, must maintain dynamic homeostasis to survive within changing environments. Even the simplest multicellular eukaryotes like sponges and cnidarians have developed cells that specialize in immune defenses to protect against disruptions to homeostasis. News headlines warn us of outbreaks of diseases, including Ebola, measles, flu, and insect-borne viruses such as West Nile and chikungunya, that spread rapidly through populations, often with devastating consequences. We also hear about the emergence of new infections, especially ones caused by bacteria that have evolved resistance to antibiotics.

Immune systems in animals range from a loose cluster of phagocytic cells in sponges to complex interactions of molecules, cells, tissues, and organs that provide immunity in mammals. Components of the immune system constantly search the body for signs of disease-causing microorganisms called pathogens. Immune factors mobilize, identify the nature of the pathogen, strengthen the corresponding cells and molecules to combat the infection, and then halt the immune response after the infection is cleared to avoid unnecessary host cell damage. Because of its programmable memory system, the immune system can remember pathogens and initiate a more rapid response upon re-exposure. The immune response can be either innate or adaptive. The adaptive immune response stores information about past infections and mounts pathogen-specific defense. The innate immune response is always present and defends against all pathogens.

Despite the barriers of skin, tears, and mucus, pathogens may still enter the body. The innate immune system responds with inflammation, pathogen engulfment, and secretion of immune factors and proteins. Several types of cells are involved in the innate immune system, including mast cells that release histamines (causing those annoying symptoms associated with allergies and colds), macrophages that consume pathogens and cancer cells, natural killer (NK) cells that destroy tumor cells and virus-infected cells, several types of white blood cells, and even protective proteins like complement and interferon. We know from experience, however, that these barriers can fail. Fortunately, adaptive immune responses provide another, more specific line of defense.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

**Learning Objective**

**2.30** The student can create representations or models to describe nonspecific immune defenses in animals.

The immune system comprises both innate and adaptive immune responses. **Innate immunity** occurs naturally because of genetic factors or physiology; it is not induced by infection or vaccination but works to reduce the workload for the adaptive immune response. Both the innate and adaptive levels of the immune response involve secreted proteins, receptor-mediated signaling, and intricate cell-to-cell communication. The innate immune system developed early in animal evolution, roughly a billion years ago, as an essential response to infection. Innate immunity has a limited number of specific targets: any pathogenic threat triggers a consistent sequence of events that can identify the type of pathogen and either clear the infection independently or mobilize a highly specialized adaptive immune response. For example, tears and mucus secretions contain microbicidal factors.

## Physical and Chemical Barriers

Before any immune factors are triggered, the skin functions as a continuous, impassable barrier to potentially infectious pathogens. Pathogens are killed or inactivated on the skin by desiccation (drying out) and by the skin's acidity. In addition, beneficial microorganisms that coexist on the skin compete with invading pathogens, preventing infection. Regions of the body that are not protected by skin (such as the eyes and mucus membranes) have alternative methods of defense, such as tears and mucus secretions that trap and rinse away pathogens, and cilia in the nasal passages and respiratory tract that push the mucus with the pathogens out of the body. Throughout the body are other defenses, such as the low pH of the stomach (which inhibits the growth of pathogens), blood proteins that bind and disrupt bacterial cell membranes, and the process of urination (which flushes pathogens from the urinary tract).

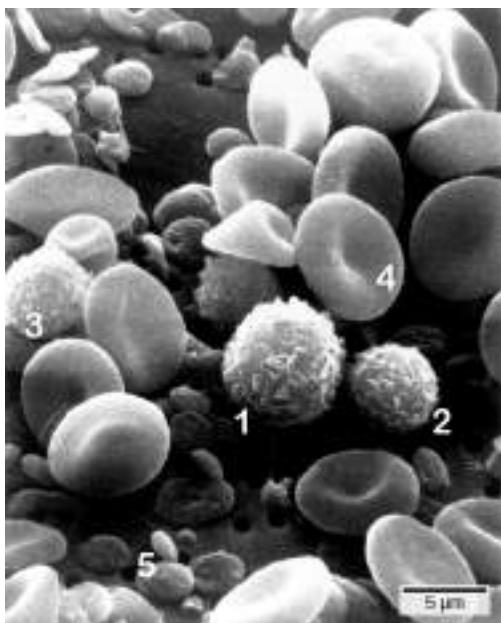

Despite these barriers, pathogens may enter the body through skin abrasions or punctures, or by collecting on mucosal surfaces in large numbers that overcome the mucus or cilia. Some pathogens have evolved specific mechanisms that allow them to overcome physical and chemical barriers. When pathogens do enter the body, the innate immune system responds with inflammation, pathogen engulfment, and secretion of immune factors and proteins.

## Pathogen Recognition

An infection may be intracellular or extracellular, depending on the pathogen. All viruses infect cells and replicate within those cells (intracellularly), whereas bacteria and other parasites may replicate intracellularly or extracellularly, depending on the species. The innate immune system must respond accordingly: by identifying the extracellular pathogen and/or by identifying host cells that have already been infected. When a pathogen enters the body, cells in the blood and lymph detect the specific **pathogen-associated molecular patterns (PAMPs)** on the pathogen's surface. PAMPs are carbohydrate, polypeptide, and nucleic acid "signatures" that are expressed by viruses, bacteria, and parasites but which differ from molecules on host cells. The immune system has specific cells, described in [Figure 33.2](#) and shown in [Figure 33.3](#), with receptors that recognize these PAMPs. A **macrophage** is a large phagocytic cell that engulfs foreign particles and pathogens. Macrophages recognize PAMPs via complementary **pattern recognition receptors (PRRs)**. PRRs are molecules on macrophages and dendritic cells which are in contact with the external environment. A **monocyte** is a type of white blood cell that circulates in the blood and lymph and differentiates into macrophages after it moves into infected tissue. Dendritic cells bind molecular signatures of pathogens and promote pathogen engulfment and destruction. Toll-like receptors (TLRs) are a type of PRR that recognizes molecules that are shared by pathogens but distinguishable from host molecules. TLRs are present in invertebrates as well as vertebrates, and appear to be one of the most ancient components of the immune system. TLRs have also been identified in the mammalian nervous system.

| Cell type           | Characteristics                                                                                                                                                                                                                                  | Location                                                                                                                        | Image                                                                                 |
|---------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------|
| Mast cell           | Dilates blood vessels and induces inflammation through release of histamines and heparin. Recruits macrophages and neutrophils. Involved in wound healing and defense against pathogens but can also be responsible for allergic reactions.      | Connective tissues, mucous membranes                                                                                            |    |
| Macrophage          | Phagocytic cell that consumes foreign pathogens and cancer cells. Stimulates response of other immune cells.                                                                                                                                     | Migrates from blood vessels into tissues.                                                                                       |    |
| Natural killer cell | Kills tumor cells and virus-infected cells.                                                                                                                                                                                                      | Circulates in blood and migrates into tissues.                                                                                  |    |
| Dendritic cell      | Presents antigens on its surface, thereby triggering adaptive immunity.                                                                                                                                                                          | Present in epithelial tissue, including skin, lung and tissues of the digestive tract. Migrates to lymph nodes upon activation. |    |
| Monocyte            | Differentiates into macrophages and dendritic cells in response to inflammation.                                                                                                                                                                 | Stored in spleen, moves through blood vessels to infected tissues.                                                              |  |
| Neutrophil          | First responders at the site of infection or trauma, this abundant phagocytic cell represents 50-60 percent of all leukocytes. Releases toxins that kill or inhibit bacteria and fungi and recruits other immune cells to the site of infection. | Migrates from blood vessels into tissues.                                                                                       |  |
| Basophil            | Responsible for defense against parasites. Releases histamines that cause inflammation and may be responsible for allergic reactions.                                                                                                            | Circulates in blood and migrates to tissues.                                                                                    |  |
| Eosinophil          | Releases toxins that kill bacteria and parasites but also causes tissue damage.                                                                                                                                                                  | Circulates in blood and migrates to tissues.                                                                                    |  |

### Effects of Cytokine Release

The binding of PRRs with PAMPs triggers the release of cytokines, which signal that a pathogen is present and needs to be destroyed along with any infected cells. A **cytokine** is a chemical messenger that regulates cell differentiation (form and function), proliferation (production), and gene expression to affect immune responses. At least 40 types of cytokines exist in humans that differ in terms of the cell type that produces them, the cell type that responds to them, and the changes they produce. One type cytokine, interferon, is illustrated in **Figure 33.4**.

One subclass of cytokines is the interleukin (IL), so named because they mediate interactions between leukocytes (white blood cells). Interleukins are involved in bridging the innate and adaptive immune responses. In addition to being released from cells after PAMP recognition, cytokines are released by the infected cells which bind to nearby uninfected cells and induce those cells to release cytokines, which results in a cytokine burst.

A second class of early-acting cytokines is interferons, which are released by infected cells as a warning to nearby uninfected cells. One of the functions of an **interferon** is to inhibit viral replication. They also have other important functions, such as tumor surveillance. Interferons work by signaling neighboring uninfected cells to destroy RNA and reduce protein synthesis, signaling neighboring infected cells to undergo apoptosis (programmed cell death), and activating immune cells.

In response to interferons, uninfected cells alter their gene expression, which increases the cells' resistance to infection. One effect of interferon-induced gene expression is a sharply reduced cellular protein synthesis. Virally infected cells produce more viruses by synthesizing large quantities of viral proteins. Thus, by reducing protein synthesis, a cell becomes resistant to viral infection.

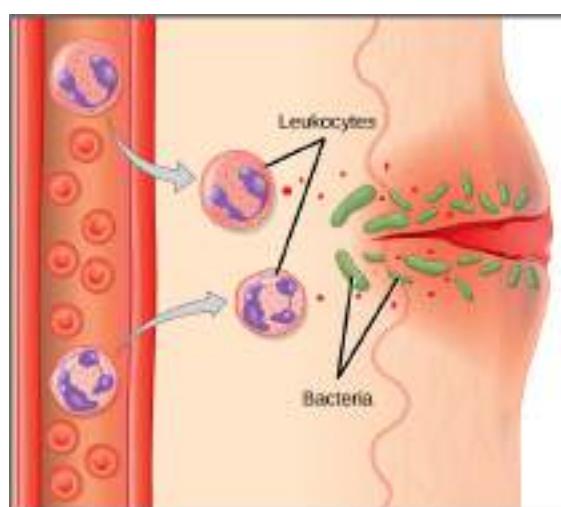

**Figure 33.4** Interferons are cytokines that are released by a cell infected with a virus. Response of neighboring cells to interferon helps stem the infection.

### Phagocytosis and Inflammation

The first cytokines to be produced are pro-inflammatory; that is, they encourage **inflammation**, the localized redness, swelling, heat, and pain that result from the movement of leukocytes and fluid through increasingly permeable capillaries to a site of infection. The population of leukocytes that arrives at an infection site depends on the nature of the infecting pathogen. Both macrophages and dendritic cells engulf pathogens and cellular debris through phagocytosis. A **neutrophil** is also a phagocytic leukocyte that engulfs and digests pathogens. Neutrophils, shown in **Figure 33.3**, are the most abundant leukocytes of the immune system. Neutrophils have a nucleus with two to five lobes, and they contain organelles, called lysosomes, that digest engulfed pathogens. An **eosinophil** is a leukocyte that works with other eosinophils to surround a parasite; it is involved in the allergic response and in protection against helminthes (parasitic worms).

Neutrophils and eosinophils are particularly important leukocytes that engulf large pathogens, such as bacteria and fungi. A **mast cell** is a leukocyte that produces inflammatory molecules, such as histamine, in response to large pathogens. A **basophil** is a leukocyte that, like a neutrophil, releases chemicals to stimulate the inflammatory response as illustrated in **Figure 33.5**. Basophils are also involved in allergy and hypersensitivity responses and induce specific types of inflammatory responses. Eosinophils and basophils produce additional inflammatory mediators to recruit more leukocytes. A hypersensitive immune response to harmless antigens, such as in pollen, often involves the release of histamine by basophils and mast cells.

**Figure 33.5** In response to a cut, mast cells secrete histamines that cause nearby capillaries to dilate. Neutrophils and monocytes leave the capillaries. Monocytes mature into macrophages. Neutrophils, dendritic cells and macrophages release chemicals to stimulate the inflammatory response. Neutrophils and macrophages also consume invading bacteria by phagocytosis.

Cytokines also send feedback to cells of the nervous system to bring about the overall symptoms of feeling sick, which include lethargy, muscle pain, and nausea. These effects may have evolved because the symptoms encourage the individual to rest and prevent them from spreading the infection to others. Cytokines also increase the core body temperature, causing a fever, which causes the liver to withhold iron from the blood. Without iron, certain pathogens, such as some bacteria, are unable to replicate; this is called nutritional immunity.

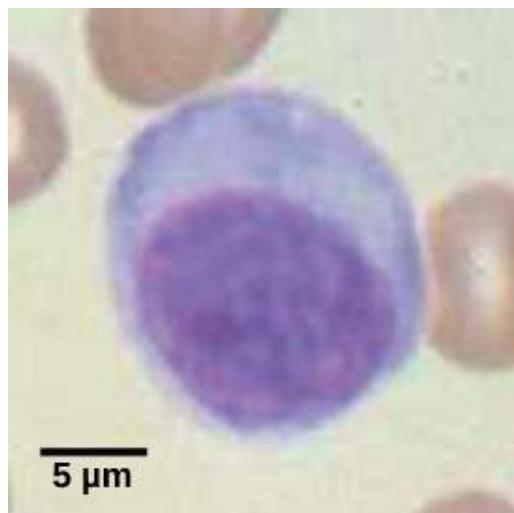

Watch this 23-second stop-motion [video](http://openstaxcollege.org/l/conidia) (<http://openstaxcollege.org/l/conidia>) showing a neutrophil that searches for and engulfs fungus spores during an elapsed time of about 79 minutes.

How does the action shown in the video clip (<http://openstaxcollege.org/l/conidia> (<http://openstaxcollege.org/l/conidia>)) demonstrate an immune response?

- a. Neutrophils phagocytize pathogens invading the body and release chemical histamines that cause pathogen destruction and removal from the body. This prevents pathogens from producing toxic compounds that harm cells.
- b. Neutrophils phagocytize pathogens invading the body, resulting in their death and removal from the body. This prevents pathogens from multiplying or producing toxic compounds that harm human cells.
- c. Neutrophils are phagocytic and are the first responders to infection. They produce large quantities of cytokines, which cause pathogen destruction and removal from the body.
- d. Neutrophils produce cytokines that help phagocytes to recognize foreign material that will destroy and remove pathogens from the body.

## Natural Killer Cells

**Lymphocytes** are leukocytes that are histologically identifiable by their large, darkly staining nuclei; they are small cells with very little cytoplasm, as shown in [Figure 33.6](#). Infected cells are identified and destroyed by **natural killer (NK) cells**, lymphocytes that can kill cells infected with viruses or tumor cells (abnormal cells that uncontrollably divide and invade other tissue). T cells and B cells of the adaptive immune system also are classified as lymphocytes. **T cells** are lymphocytes that mature in the thymus gland, and **B cells** are lymphocytes that mature in the bone marrow. NK cells identify intracellular infections, especially from viruses, by the altered expression of **major histocompatibility class (MHC) I molecules** on the surface of infected cells. MHC I molecules are proteins on the surfaces of all nucleated cells, thus they are scarce on red blood cells and platelets which are non-nucleated. The function of MHC I molecules is to display fragments of proteins from the infectious agents within the cell to T-cells; healthy cells will be ignored, while “non-self” or foreign proteins will be attacked by the immune system. MHC II molecules are found mainly on cells containing antigens (“non-self proteins”) and on lymphocytes. **MHC II molecules** interact with helper T-cells to trigger the appropriate immune response, which may include the inflammatory response.

**Figure 33.6** Lymphocytes, such as NK cells, are characterized by their large nuclei that actively absorb Wright stain and therefore appear dark colored under a microscope.

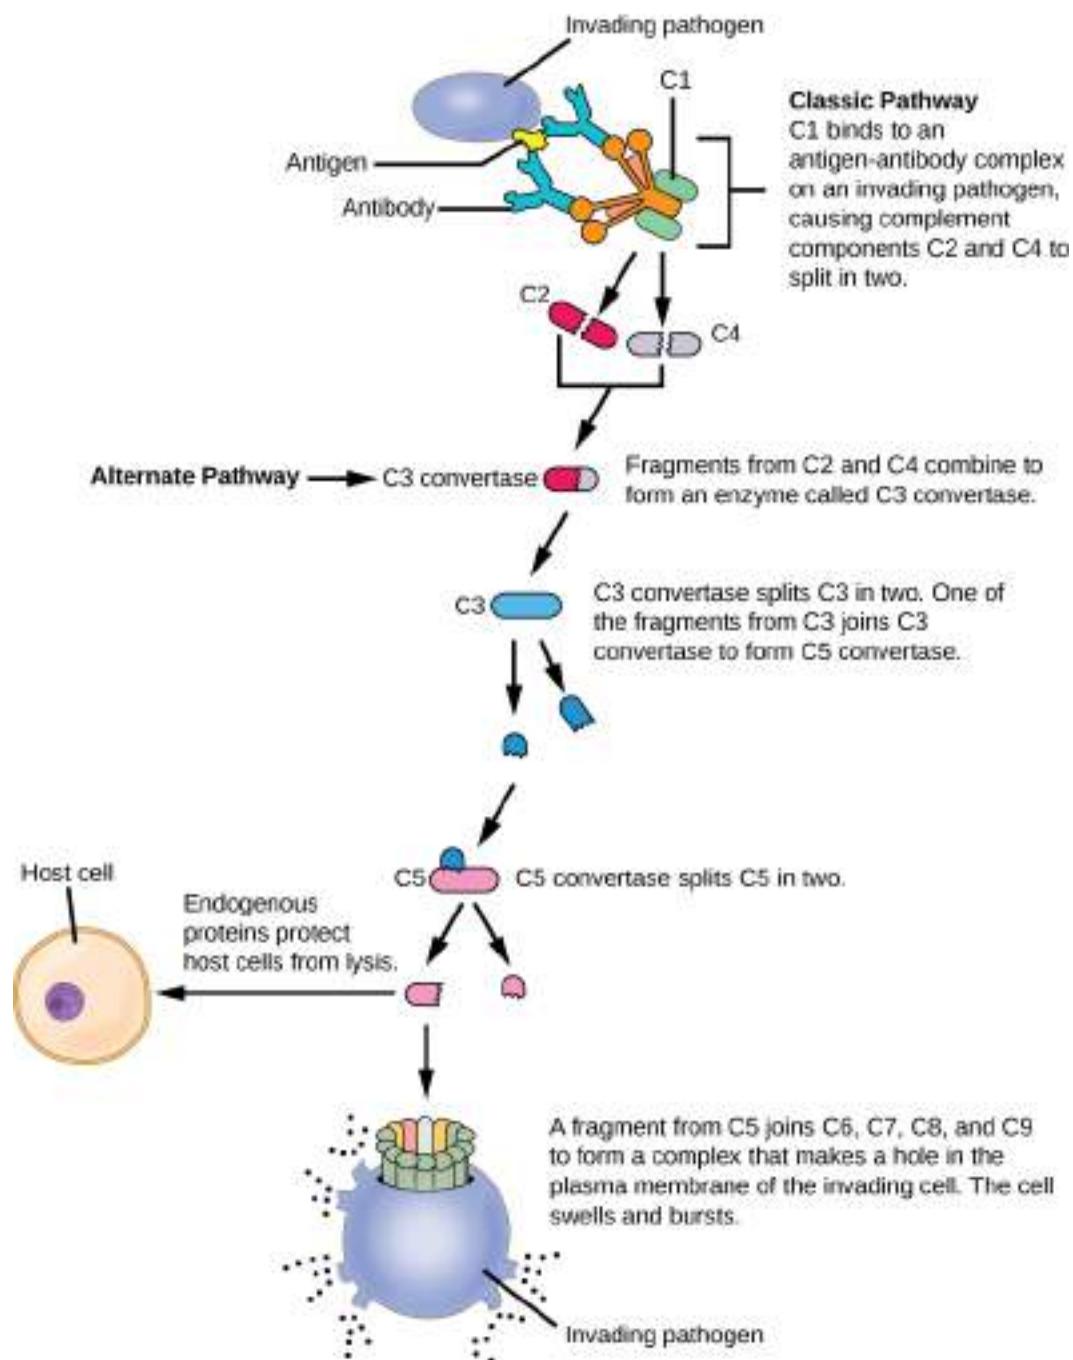

An infected cell (or a tumor cell) is usually incapable of synthesizing and displaying MHC I molecules appropriately. The metabolic resources of cells infected by some viruses produce proteins that interfere with MHC I processing and/or trafficking to the cell surface. The reduced MHC I on host cells varies from virus to virus and results from active inhibitors being produced by the viruses. This process can deplete host MHC I molecules on the cell surface, which NK cells detect as “unhealthy” or “abnormal” while searching for cellular MHC I molecules. Similarly, the dramatically altered gene expression of tumor cells leads to expression of extremely deformed or absent MHC I molecules that also signal “unhealthy” or “abnormal.”

NK cells are always active; an interaction with normal, intact MHC I molecules on a healthy cell disables the killing sequence, and the NK cell moves on. After the NK cell detects an infected or tumor cell, its cytoplasm secretes granules comprised of **perforin**, a destructive protein that creates a pore in the target cell. Granzymes are released along with the perforin in the immunological synapse. A **granzyme** is a protease that digests cellular proteins and induces the target cell to undergo programmed cell death, or apoptosis. Phagocytic cells then digest the cell debris left behind. NK cells are constantly patrolling the body and are an effective mechanism for controlling potential infections and preventing cancer progression.

## Complement

An array of approximately 20 types of soluble proteins, called a **complement system**, functions to destroy extracellular pathogens. Cells of the liver and macrophages synthesize complement proteins continuously; these proteins are abundant in the blood serum and are capable of responding immediately to infecting microorganisms. The complement system is so named because it is complementary to the antibody response of the adaptive immune system. Complement proteins bind to the surfaces of microorganisms and are particularly attracted to pathogens that are already bound by antibodies. Binding of complement proteins occurs in a specific and highly regulated sequence, with each successive protein being activated by cleavage and/or structural changes induced upon binding of the preceding protein(s). After the first few complement proteins bind, a cascade of sequential binding events follows in which the pathogen rapidly becomes coated in complement proteins.

Complement proteins perform several functions. The proteins serve as a marker to indicate the presence of a pathogen to phagocytic cells, such as macrophages and B cells, and enhance engulfment; this process is called **opsonization**. Certain complement proteins can combine to form attack complexes that open pores in microbial cell membranes. These structures destroy pathogens by causing their contents to leak, as illustrated in **Figure 33.7**.

**Figure 33.7** The classic pathway for the complement cascade involves the attachment of several initial complement proteins to an antibody-bound pathogen followed by rapid activation and binding of many more complement proteins and the creation of destructive pores in the microbial cell envelope and cell wall. The alternate pathway does not involve antibody activation. Rather, C3 convertase spontaneously breaks down C3. Endogenous regulatory proteins prevent the complement complex from binding to host cells. Pathogens lacking these regulatory proteins are lysed. (credit: modification of work by NIH)

## 33.2 | Adaptive Immune Response

In this section, you will explore the following questions:

- What is adaptive immunity?
- What is the difference between adaptive and innate immunity?
- What are the cell-mediated immune response and the humoral immune response?
- What is immune tolerance?

### Connection for AP® Courses

Adaptive immune response takes days or even weeks to become established—much longer than the innate response—and is more specific to pathogens and involves molecular memory. This type of immunity occurs after we've been exposed to an antigen either from a pathogen or through vaccination and is activated when the innate immune response is insufficient to control the infection. There are two types of adaptive responses: **cell-mediated immune response**, carried out by T cells, and the **humoral immune response**, controlled by activated B cells and their production of antibodies. **Adaptive immunity** involves memory so that re-exposure to the same pathogen will elicit an efficient and quick response. This gives long-term protection from reinfection.

The information in this section will seem overwhelmingly complex with its discussion of antigens, antigen-presenting cells, major histocompatibility (MHC) molecules, different types of T cells, antibody-secreting B cells, and the programming of memory cells. One suggestion is to read the information slowly, study the figures and their captions carefully, and make your own series of diagrams. Despite the difficulty of the information, many concepts will seem familiar, such as the role of proteins embedded in plasma cell membranes and interactions among different types of cells and molecules.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 and Big Idea 3 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

## Antigen-presenting Cells

Unlike NK cells of the innate immune system, B cells (B lymphocytes) are a type of white blood cell that gives rise to antibodies, whereas T cells (T lymphocytes) are a type of white blood cell that plays an important role in the immune response. T cells are a key component in the cell-mediated response—the specific immune response that utilizes T cells to neutralize cells that have been infected with viruses and certain bacteria. There are three types of T cells: cytotoxic, helper, and suppressor T cells. Cytotoxic T cells destroy virus-infected cells in the cell-mediated immune response, and helper T cells play a part in activating both the antibody and the cell-mediated immune responses. Suppressor T cells deactivate T cells and B cells when needed, and thus prevent the immune response from becoming too intense.

An **antigen** is a foreign or “non-self” macromolecule that reacts with cells of the immune system. Not all antigens will provoke a response. For instance, individuals produce innumerable “self” antigens and are constantly exposed to harmless foreign antigens, such as food proteins, pollen, or dust components. The suppression of immune responses to harmless macromolecules is highly regulated and typically prevents processes that could be damaging to the host, known as tolerance.

The innate immune system contains cells that detect potentially harmful antigens, and then inform the adaptive immune response about the presence of these antigens. An **antigen-presenting cell (APC)** is an immune cell that detects, engulfs, and informs the adaptive immune response about an infection. When a pathogen is detected, these APCs will phagocytose the pathogen and digest it to form many different fragments of the antigen. Antigen fragments will then be transported to the surface of the APC, where they will serve as an indicator to other immune cells. **Dendritic cells** are immune cells that process antigen material; they are present in the skin (Langerhans cells) and the lining of the nose, lungs, stomach, and intestines. Sometimes a dendritic cell presents on the surface of other cells to induce an immune response, thus functioning as an antigen-presenting cell. Macrophages also function as APCs. Before activation and differentiation, B cells can also function as APCs.

After phagocytosis by APCs, the phagocytic vesicle fuses with an intracellular lysosome forming phagolysosome. Within the phagolysosome, the components are broken down into fragments; the fragments are then loaded onto MHC class I or MHC class II molecules and are transported to the cell surface for antigen presentation, as illustrated in **Figure 33.8**. Note that T lymphocytes cannot properly respond to the antigen unless it is processed and embedded in an MHC II molecule. APCs express MHC on their surfaces, and when combined with a foreign antigen, these complexes signal a “non-self” invader. Once the fragment of antigen is embedded in the MHC II molecule, the immune cell can respond. Helper T- cells are one of the main lymphocytes that respond to antigen-presenting cells. Recall that all other nucleated cells of the body expressed MHC I molecules, which signal “healthy” or “normal.”

**Figure 33.8** An APC, such as a macrophage, engulfs and digests a foreign bacterium. An antigen from the bacterium is presented on the cell surface in conjunction with an MHC II molecule. Lymphocytes of the adaptive immune response interact with antigen-embedded MHC II molecules to mature into functional immune cells.

This [animation](http://openstaxcollege.org/l/immune_system) ([http://openstaxcollege.org/l/immune\\_system](http://openstaxcollege.org/l/immune_system)) from Rockefeller University shows how dendritic cells act as sentinels in the body's immune system.

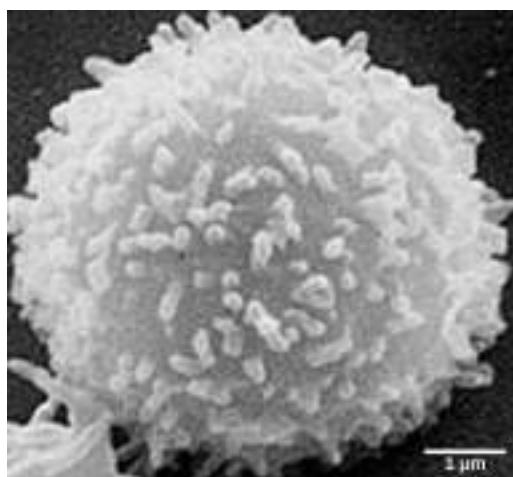

What key role do dendritic cells play in the human immune response?

- Dendritic cells directly kill infected cells and emit cytokines, which amplify the immune response.
- Dendritic cells recognize foreign proteins and prepare them to be displayed to immune cells in the lymph. This activates an immune response.
- Dendritic cells identify tumor cells or cells infected with viruses and destroy them.
- Dendritic cells act as phagocytes. They engulf and digest pathogens.

## T and B Lymphocytes

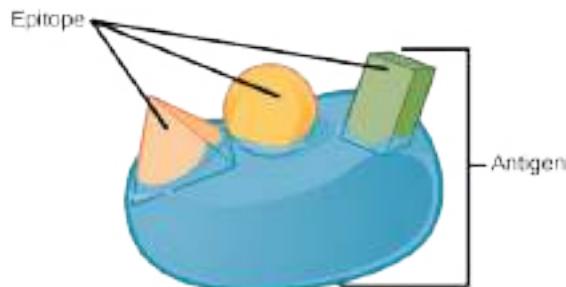

Lymphocytes in human circulating blood are approximately 80 to 90 percent T cells, shown in **Figure 33.9**, and 10 to 20 percent B cells. Recall that the T cells are involved in the cell-mediated immune response, whereas B cells are part of the humoral immune response.

T cells encompass a heterogeneous population of cells with extremely diverse functions. Some T cells respond to APCs of the innate immune system, and indirectly induce immune responses by releasing cytokines. Other T cells stimulate B cells to prepare their own response. Another population of T cells detects APC signals and directly kills the infected cells. Other T cells are involved in suppressing inappropriate immune reactions to harmless or “self” antigens.

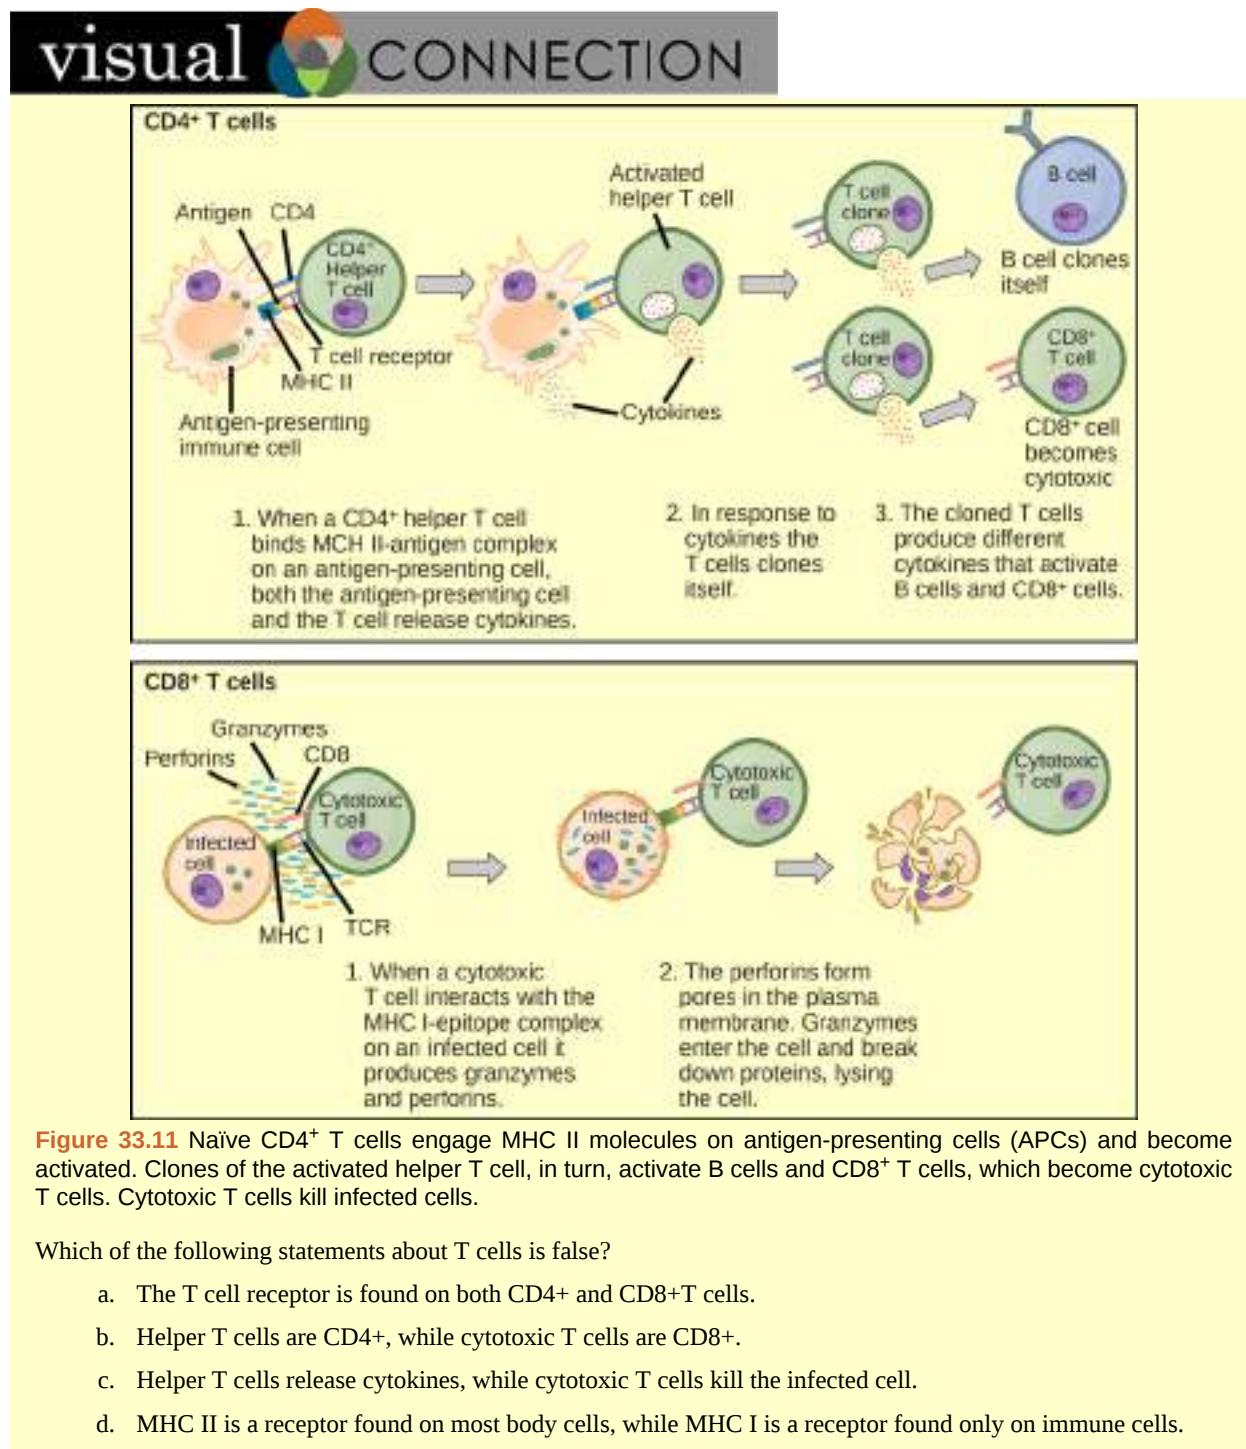

**Figure 33.9** This scanning electron micrograph shows a T lymphocyte, which is responsible for the cell-mediated immune response. T cells are able to recognize antigens. (credit: modification of work by NCI; scale-bar data from Matt Russell)

T and B cells exhibit a common theme of recognition/binding of specific antigens via a complementary receptor, followed by activation and self-amplification/maturation to specifically bind to the particular antigen of the infecting pathogen. T and B lymphocytes are also similar in that each cell only expresses one type of antigen receptor. Any individual may possess a population of T and B cells that together express a near limitless variety of antigen receptors that are capable of recognizing virtually any infecting pathogen. T and B cells are activated when they recognize small components of antigens, called **epitopes**, presented by APCs, illustrated in **Figure 33.10**. Note that recognition occurs at a specific epitope rather than on the entire antigen; for this reason, epitopes are known as “antigenic determinants.” In the absence of information from APCs, T and B cells remain inactive, or naïve, and are unable to prepare an immune response. The requirement for information from the APCs of innate immunity to trigger B cell or T cell activation illustrates the essential nature of the innate immune response to the functioning of the entire immune system.

**Figure 33.10** An antigen is a macromolecule that reacts with components of the immune system. A given antigen may contain several motifs that are recognized by immune cells. Each motif is an epitope. In this figure, the entire structure is an antigen, and the orange, salmon and green components projecting from it represent potential epitopes.

Naïve T cells can express one of two different molecules, CD4 or CD8, on their surface, as shown in **Figure 33.11**, and are accordingly classified as CD4<sup>+</sup> or CD8<sup>+</sup> cells. These molecules are important because they regulate how a T cell will interact with and respond to an APC. Naïve CD4<sup>+</sup> cells bind APCs via their antigen-embedded MHC II molecules and are stimulated to become **helper T (T<sub>H</sub>) lymphocytes**, cells that go on to stimulate B cells (or cytotoxic T cells) directly or secrete cytokines to inform more and various target cells about the pathogenic threat. In contrast, CD8<sup>+</sup> cells engage antigen-embedded MHC I molecules on APCs and are stimulated to become **cytotoxic T lymphocytes (CTLs)**, which directly kill infected cells by apoptosis and emit cytokines to amplify the immune response. The two populations of T cells have different mechanisms of immune protection, but both bind MHC molecules via their antigen receptors called T cell receptors (TCRs). The CD4 or CD8 surface molecules differentiate whether the TCR will engage an MHC II or an MHC I molecule. Because they assist in binding specificity, the CD4 and CD8 molecules are described as coreceptors.

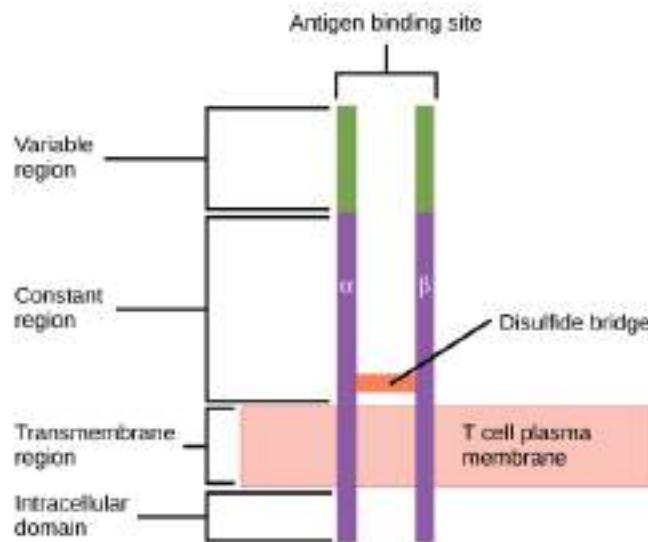

**Figure 33.11** Naïve CD4<sup>+</sup> T cells engage MHC II molecules on antigen-presenting cells (APCs) and become activated. Clones of the activated helper T cell, in turn, activate B cells and CD8<sup>+</sup> T cells, which become cytotoxic T cells. Cytotoxic T cells kill infected cells.

Which of the following statements about T cells is false?

- The T cell receptor is found on both CD4<sup>+</sup> and CD8<sup>+</sup> T cells.
- Helper T cells are CD4<sup>+</sup>, while cytotoxic T cells are CD8<sup>+</sup>.
- Helper T cells release cytokines, while cytotoxic T cells kill the infected cell.
- MHC II is a receptor found on most body cells, while MHC I is a receptor found only on immune cells.

Consider the innumerable possible antigens that an individual will be exposed to during a lifetime. The mammalian adaptive immune system is adept in responding appropriately to each antigen. Mammals have an enormous diversity of T cell populations, resulting from the diversity of TCRs. Each TCR consists of two polypeptide chains that span the T cell membrane, as illustrated in **Figure 33.12**; the chains are linked by a disulfide bridge. Each polypeptide chain is comprised of a constant domain and a variable domain: a domain, in this sense, is a specific region of a protein that may be regulatory or structural. The intracellular domain is involved in intracellular signaling. A single T cell will express thousands of identical copies of one specific TCR variant on its cell surface. The specificity of the adaptive immune system occurs because it synthesizes millions of different T cell populations, each expressing a TCR that differs in its variable domain. This TCR

diversity is achieved by the mutation and recombination of genes that encode these receptors in stem cell precursors of T cells. The binding between an antigen-displaying MHC molecule and a complementary TCR “match” indicates that the adaptive immune system needs to activate and produce that specific T cell because its structure is appropriate to recognize and destroy the invading pathogen.

**Figure 33.12** A T cell receptor spans the membrane and projects variable binding regions into the extracellular space to bind processed antigens via MHC molecules on APCs.

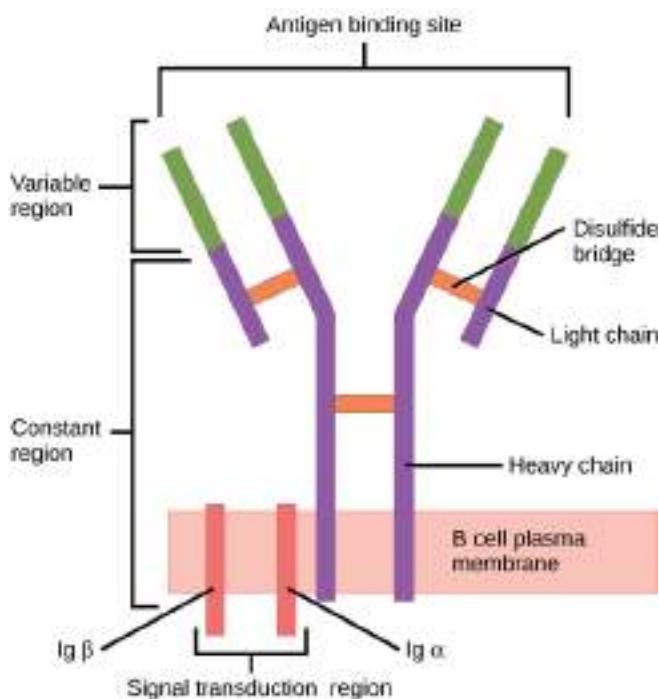

### Helper T Lymphocytes

The  $T_H$  lymphocytes function indirectly to identify potential pathogens for other cells of the immune system. These cells are important for extracellular infections, such as those caused by certain bacteria, helminths, and protozoa.  $T_H$  lymphocytes recognize specific antigens displayed in the MHC II complexes of APCs. There are two major populations of  $T_H$  cells:  $T_{H1}$  and  $T_{H2}$ .  $T_{H1}$  cells secrete cytokines to enhance the activities of macrophages and other T cells.  $T_{H1}$  cells activate the action of cytotoxic T cells, as well as macrophages.  $T_{H2}$  cells stimulate naïve B cells to destroy foreign invaders via antibody secretion. Whether a  $T_{H1}$  or a  $T_{H2}$  immune response develops depends on the specific types of cytokines secreted by cells of the innate immune system, which in turn depends on the nature of the invading pathogen.

The  $T_{H1}$ -mediated response involves macrophages and is associated with inflammation. Recall the frontline defenses of macrophages involved in the innate immune response. Some intracellular bacteria, such as *Mycobacterium tuberculosis*, have evolved to multiply in macrophages after they have been engulfed. These pathogens evade attempts by macrophages to destroy and digest the pathogen. When *M. tuberculosis* infection occurs, macrophages can stimulate naïve T cells to become  $T_{H1}$  cells. These stimulated T cells secrete specific cytokines that send feedback to the macrophage to stimulate its digestive capabilities and allow it to destroy the colonizing *M. tuberculosis*. In the same manner,  $T_{H1}$ -activated macrophages also become better suited to ingest and kill tumor cells. In summary;  $T_{H1}$  responses are directed toward intracellular invaders while  $T_{H2}$  responses are aimed at those that are extracellular.

### B Lymphocytes

When stimulated by the  $T_{H2}$  pathway, naïve B cells differentiate into antibody-secreting plasma cells. A **plasma cell** is an immune cell that secretes antibodies; these cells arise from B cells that were stimulated by antigens. Similar to T cells, naïve B cells initially are coated in thousands of B cell receptors (BCRs), which are membrane-bound forms of Ig (immunoglobulin, or an antibody). The B cell receptor has two heavy chains and two light chains connected by disulfide linkages. Each chain has a constant and a variable region; the latter is involved in antigen binding. Two other membrane proteins, Ig alpha and Ig beta, are involved in signaling. The receptors of any particular B cell, as shown in **Figure 33.13** are all the same, but the hundreds of millions of different B cells in an individual have distinct recognition domains that contribute to extensive diversity in the types of molecular structures to which they can bind. In this state, B cells function as APCs. They bind and engulf foreign antigens via their BCRs and then display processed antigens in the context of MHC II molecules to  $T_{H2}$  cells. When a  $T_{H2}$  cell detects that a B cell is bound to a relevant antigen, it secretes specific cytokines that induce the B cell to proliferate rapidly, which makes thousands of identical (clonal) copies of it, and then it synthesizes and secretes antibodies with the same antigen recognition pattern as the BCRs. The activation of B cells corresponding to one specific BCR variant and the dramatic proliferation of that variant is known as **clonal selection**. This phenomenon drastically, but briefly, changes the proportions of BCR variants expressed by the immune system, and shifts the balance toward BCRs specific to the infecting pathogen.

**Figure 33.13** B cell receptors are embedded in the membranes of B cells and bind a variety of antigens through their variable regions. The signal transduction region transfers the signal into the cell.

T and B cells differ in one fundamental way: whereas T cells bind antigens that have been digested and embedded in MHC molecules by APCs, B cells function as APCs that bind intact antigens that have not been processed. Although T and B cells both react with molecules that are termed “antigens,” these lymphocytes actually respond to very different types of molecules. B cells must be able to bind intact antigens because they secrete antibodies that must recognize the pathogen directly, rather than digested remnants of the pathogen. Bacterial carbohydrate and lipid molecules can activate B cells independently from the T cells.

### Cytotoxic T Lymphocytes

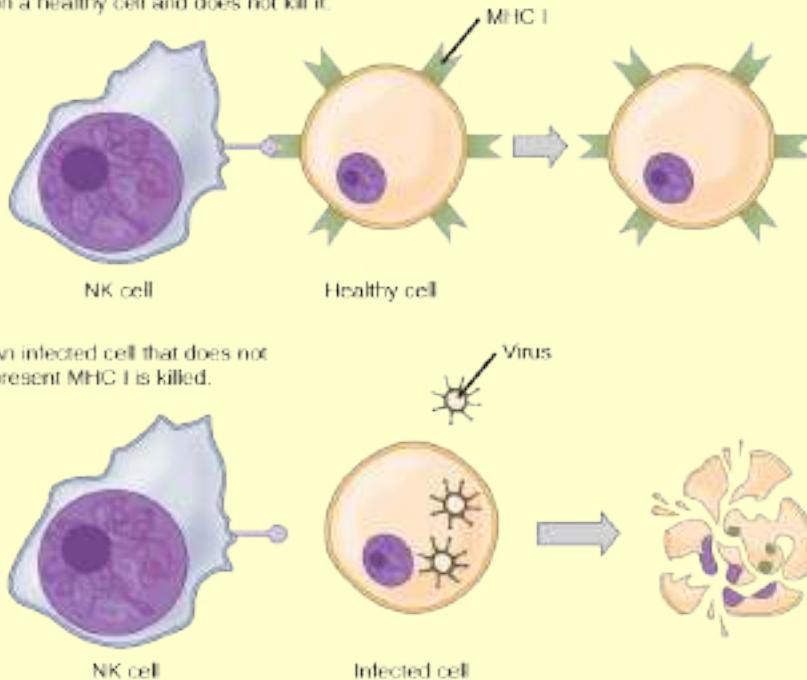

CTLs, a subclass of T cells, function to clear infections directly. The cell-mediated part of the adaptive immune system consists of CTLs that attack and destroy infected cells. CTLs are particularly important in protecting against viral infections; this is because viruses replicate within cells where they are shielded from extracellular contact with circulating antibodies. When APCs phagocytize pathogens and present MHC I-embedded antigens to naïve CD8<sup>+</sup> T cells that express complementary TCRs, the CD8<sup>+</sup> T cells become activated to proliferate according to clonal selection. These resulting CTLs then identify non-APCs displaying the same MHC I-embedded antigens (for example, viral proteins)—for example, the CTLs identify infected host cells.

Intracellularly, infected cells typically die after the infecting pathogen replicates to a sufficient concentration and lyses the cell, as many viruses do. CTLs attempt to identify and destroy infected cells before the pathogen can replicate and escape, thereby halting the progression of intracellular infections. CTLs also support NK lymphocytes to destroy early cancers. Cytokines secreted by the T<sub>H</sub>1 response that stimulates macrophages also stimulate CTLs and enhance their ability to identify and destroy infected cells and tumors.

CTLs sense MHC I-embedded antigens by directly interacting with infected cells via their TCRs. Binding of TCRs with antigens activates CTLs to release perforin and granzyme, degradative enzymes that will induce apoptosis of the infected cell. Recall that this is a similar destruction mechanism to that used by NK cells. In this process, the CTL does not become infected and is not harmed by the secretion of perforin and granzymes. In fact, the functions of NK cells and CTLs are complementary and maximize the removal of infected cells, as illustrated in **Figure 33.14**. If the NK cell cannot identify the “missing self” pattern of down-regulated MHC I molecules, then the CTL can identify it by the complex of MHC I with foreign antigens, which signals “altered self.” Similarly, if the CTL cannot detect antigen-embedded MHC I because the receptors are depleted from the cell surface, NK cells will destroy the cell instead. CTLs also emit cytokines, such as interferons, that alter surface protein expression in other infected cells, such that the infected cells can be easily identified and destroyed. Moreover, these interferons can also prevent virally infected cells from releasing virus particles.

visual CONNECTION

A natural killer (NK) cell recognizes MHC I on a healthy cell and does not kill it.

**Figure 33.14** Natural killer (NK) cells recognize the MHC I receptor on healthy cells. If MHC I is absent, the cell is lysed.

Based on what you know about MHC receptors, why do you think an organ transplanted from an incompatible donor to a recipient will be rejected?

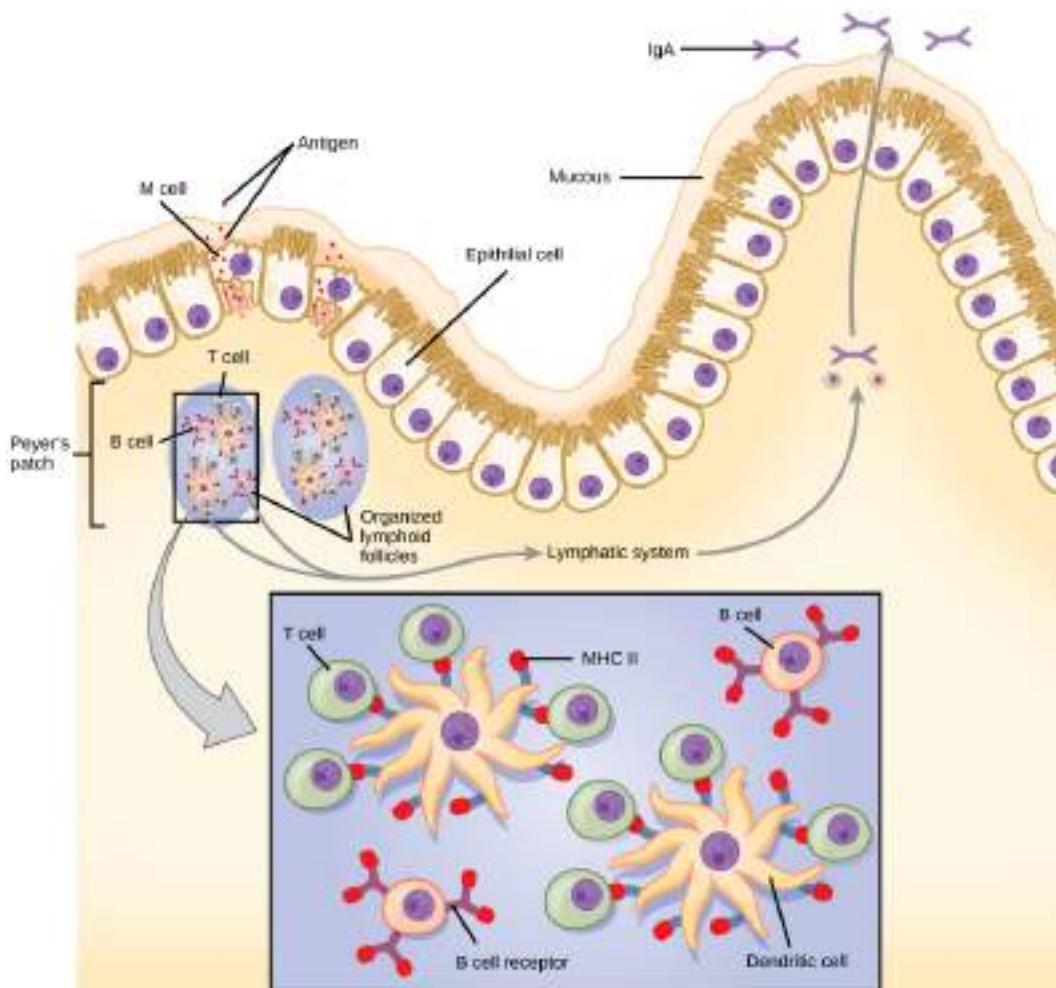

- a. The natural killer cells of the recipient will recognize the MHC II proteins present on the cell surface of incompatible organ as foreign and activate macrophages, which will phagocytose foreign cells. The attack will cause the organ to be rejected.
  - b. Neutrophils will recognize the proteins on incompatible organ as foreign and will phagocytose the foreign cells of the incompatible organ.
  - c. The natural killer cells of the recipient will recognize the MHC II proteins present on the cell surface of incompatible organ as foreign and will attack these foreign proteins. The attack will cause the organ to be rejected.
  - d. The recipient's immune system will recognize the proteins on the incompatible organ as foreign and will attack these foreign proteins. The attack will cause the organ to be rejected.

Plasma cells and CTLs are collectively called **effector cells**: they represent differentiated versions of their naïve counterparts, and they are involved in bringing about the immune defense of killing pathogens and infected host cells.

## **Mucosal Surfaces and Immune Tolerance**

The innate and adaptive immune responses discussed thus far comprise the systemic immune system (affecting the whole body), which is distinct from the mucosal immune system. Mucosal immunity is formed by mucosa-associated lymphoid tissue, which functions independently of the systemic immune system, and which has its own innate and adaptive components. **Mucosa-associated lymphoid tissue (MALT)**, illustrated in [Figure 33.15](#), is a collection of lymphatic tissue that combines with epithelial tissue lining the mucosa throughout the body. This tissue functions as the immune barrier and response in areas of the body with direct contact to the external environment. The systemic and mucosal immune systems use many of the same cell types. Foreign particles that make their way to MALT are taken up by absorptive epithelial cells called M cells and delivered to APCs located directly below the mucosal tissue. M cells function in the transport described,

and are located in the Peyer's patch, a lymphoid nodule. APCs of the mucosal immune system are primarily dendritic cells, with B cells and macrophages having minor roles. Processed antigens displayed on APCs are detected by T cells in the MALT and at various mucosal induction sites, such as the tonsils, adenoids, appendix, or the mesenteric lymph nodes of the intestine. Activated T cells then migrate through the lymphatic system and into the circulatory system to mucosal sites of infection.

**Figure 33.15** The topology and function of intestinal MALT is shown. Pathogens are taken up by M cells in the intestinal epithelium and excreted into a pocket formed by the inner surface of the cell. The pocket contains antigen-presenting cells such as dendritic cells, which engulf the antigens, then present them with MHC II molecules on the cell surface. The dendritic cells migrate to an underlying tissue called a Peyer's patch. Antigen-presenting cells, T cells, and B cells aggregate within the Peyer's patch, forming organized lymphoid follicles. There, some T cells and B cells are activated. Other antigen-loaded dendritic cells migrate through the lymphatic system where they activate B cells, T cells, and plasma cells in the lymph nodes. The activated cells then return to MALT tissue effector sites. IgA and other antibodies are secreted into the intestinal lumen.

MALT is a crucial component of a functional immune system because mucosal surfaces, such as the nasal passages, are the first tissues onto which inhaled or ingested pathogens are deposited. The mucosal tissue includes the mouth, pharynx, and esophagus, and the gastrointestinal, respiratory, and urogenital tracts.

The immune system has to be regulated to prevent wasteful, unnecessary responses to harmless substances, and more importantly so that it does not attack “self.” The acquired ability to prevent an unnecessary or harmful immune response to a detected foreign substance known not to cause disease is described as **immune tolerance**. Immune tolerance is crucial for maintaining mucosal homeostasis given the tremendous number of foreign substances (such as food proteins) that APCs of the oral cavity, pharynx, and gastrointestinal mucosa encounter. Immune tolerance is brought about by specialized APCs in the liver, lymph nodes, small intestine, and lung that present harmless antigens to an exceptionally diverse population of **regulatory T ( $T_{reg}$ ) cells**, specialized lymphocytes that suppress local inflammation and inhibit the secretion of stimulatory immune factors. The combined result of  $T_{reg}$  cells is to prevent immunologic activation and inflammation in undesired tissue

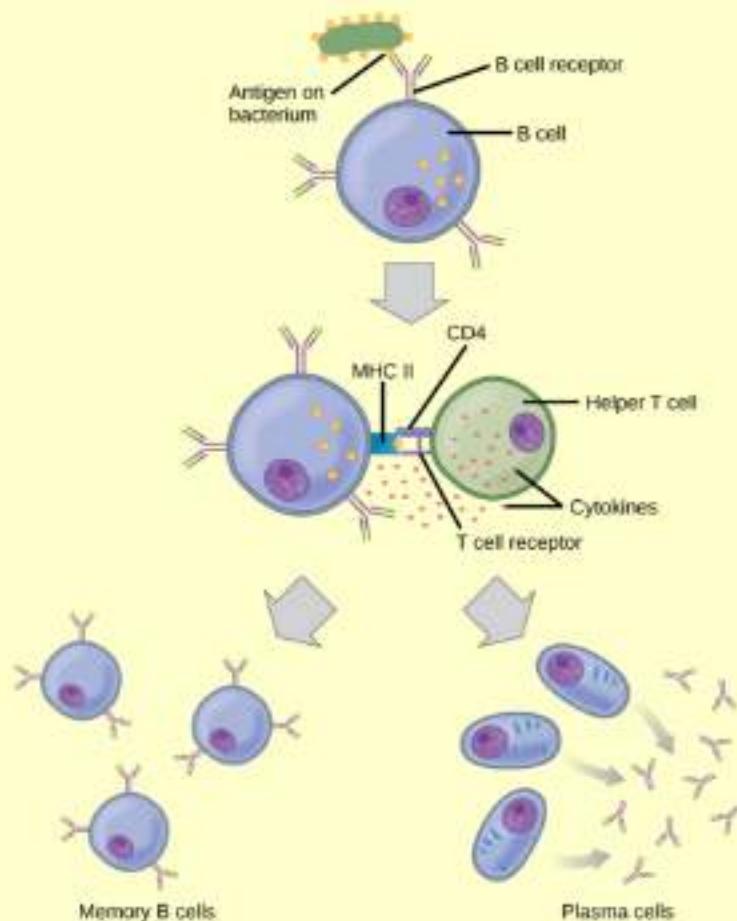

compartments and to allow the immune system to focus on pathogens instead. In addition to promoting immune tolerance of harmless antigens, other subsets of T<sub>reg</sub> cells are involved in the prevention of the **autoimmune response**, which is an inappropriate immune response to host cells or self-antigens. Another T<sub>reg</sub> class suppresses immune responses to harmful pathogens after the infection has cleared to minimize host cell damage induced by inflammation and cell lysis.

## Immunological Memory

The adaptive immune system possesses a memory component that allows for an efficient and dramatic response upon reinvasion of the same pathogen. Memory is handled by the adaptive immune system with little reliance on cues from the innate response. During the adaptive immune response to a pathogen that has not been encountered before, called a primary response, plasma cells secreting antibodies and differentiated T cells increase, then plateau over time. As B and T cells mature into effector cells, a subset of the naïve populations differentiates into B and T memory cells with the same antigen specificities, as illustrated in [Figure 33.16](#).

A **memory cell** is an antigen-specific B or T lymphocyte that does not differentiate into effector cells during the primary immune response, but that can immediately become effector cells upon re-exposure to the same pathogen. During the primary immune response, memory cells do not respond to antigens and do not contribute to host defenses. As the infection is cleared and pathogenic stimuli subside, the effectors are no longer needed, and they undergo apoptosis. In contrast, the memory cells persist in the circulation.

## visual CONNECTION

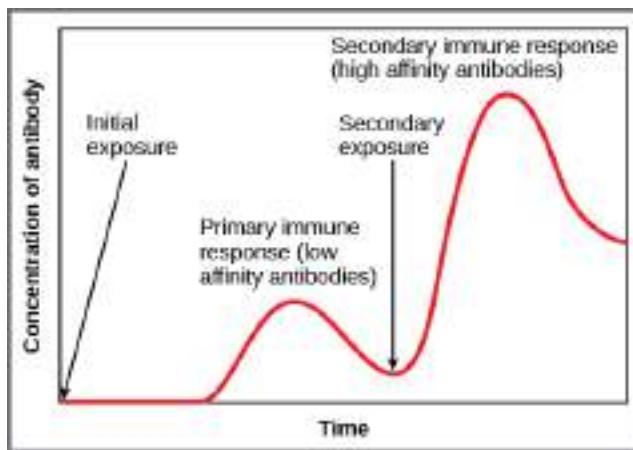

**Figure 33.16** After initially binding an antigen to the B cell receptor (BCR), a B cell internalizes the antigen and presents it on MHC II. A helper T cell recognizes the MHC II–antigen complex and activates the B cell. As a result, memory B cells and plasma cells are made.

Why are both plasma B cells and memory B cells made when helper T cells activate B cells?

- Plasma B cells produce antibodies to fight against pathogen. Memory B cells retain the information about this particular pathogen so that during the subsequent exposure to the same pathogen, a stronger response can be generated.
- Plasma B cells phagocytose the pathogen. Memory B cells retain the information about this particular pathogen so that during the subsequent exposure to the same pathogen, a stronger response can be generated.
- Plasma B cells produce antibodies to fight against a pathogen. Memory B cells retain the information about this particular pathogen so that during the subsequent exposure to the same pathogen, a stronger response can be generated, but antibodies are not produced.
- Plasma B cells produces some cytokines that allows memory B cells to recognize the pathogen and produce antibodies to fight against the pathogen.

If the pathogen is never encountered again during the individual's lifetime, B and T memory cells will circulate for a few years or even several decades and will gradually die off, having never functioned as effector cells. However, if the host is re-exposed to the same pathogen type, circulating memory cells will immediately differentiate into plasma cells and CTLs without input from APCs or  $T_H$  cells. One reason the adaptive immune response is delayed is because it takes time for naïve

B and T cells with the appropriate antigen specificities to be identified and activated. Upon reinfection, this step is skipped, and the result is a more rapid production of immune defenses. Memory B cells that differentiate into plasma cells output tens to hundreds-fold greater antibody amounts than were secreted during the primary response, as the graph in [Figure 33.17](#) illustrates. This rapid and dramatic antibody response may stop the infection before it can even become established, and the individual may not realize they had been exposed.

**Figure 33.17** In the primary response to infection, antibodies are secreted first from plasma cells. Upon re-exposure to the same pathogen, memory cells differentiate into antibody-secreting plasma cells that output a greater amount of antibody for a longer period of time.

Vaccination is based on the knowledge that exposure to noninfectious antigens, derived from known pathogens, generates a mild primary immune response. The immune response to vaccination may not be perceived by the host as illness but still confers immune memory. When exposed to the corresponding pathogen to which an individual was vaccinated, the reaction is similar to a secondary exposure. Because each reinfection generates more memory cells and increased resistance to the pathogen, and because some memory cells die, certain vaccine courses involve one or more booster vaccinations to mimic repeat exposures: for instance, tetanus boosters are necessary every ten years because the memory cells only live that long.

### Mucosal Immune Memory

A subset of T and B cells of the mucosal immune system differentiates into memory cells just as in the systemic immune system. Upon reinvasion of the same pathogen type, a pronounced immune response occurs at the mucosal site where the original pathogen deposited, but a collective defense is also organized within interconnected or adjacent mucosal tissue. For instance, the immune memory of an infection in the oral cavity would also elicit a response in the pharynx if the oral cavity was exposed to the same pathogen.

## career CONNECTION

### Vaccinologist

Vaccination (or immunization) involves the delivery, usually by injection as shown in **Figure 33.18**, of noninfectious antigen(s) derived from known pathogens. Other components, called adjuvants, are delivered in parallel to help stimulate the immune response. Immunological memory is the reason vaccines work. Ideally, the effect of vaccination is to elicit immunological memory, and thus resistance to specific pathogens without the individual having to experience an infection.

**Figure 33.18** Vaccines are often delivered by injection into the arm. (credit: U.S. Navy Photographer's Mate Airman Apprentice Christopher D. Blachly)

Vaccinologists are involved in the process of vaccine development from the initial idea to the availability of the completed vaccine. This process can take decades, can cost millions of dollars, and can involve many obstacles along the way. For instance, injected vaccines stimulate the systemic immune system, eliciting humoral and cell-mediated immunity, but have little effect on the mucosal response, which presents a challenge because many pathogens are deposited and replicate in mucosal compartments, and the injection does not provide the most efficient immune memory for these disease agents. For this reason, vaccinologists are actively involved in developing new vaccines that are applied via intranasal, aerosol, oral, or transcutaneous (absorbed through the skin) delivery methods. Importantly, mucosal-administered vaccines elicit both mucosal and systemic immunity and produce the same level of disease resistance as injected vaccines.

**Figure 33.19** The polio vaccine can be administered orally. (credit: modification of work by UNICEF Sverige)

Currently, a version of intranasal influenza vaccine is available, and the polio and typhoid vaccines can be administered orally, as shown in **Figure 33.19**. Similarly, the measles and rubella vaccines are being adapted to aerosol delivery using inhalation devices. Eventually, transgenic plants may be engineered to produce vaccine antigens that can be eaten to confer disease resistance. Other vaccines may be adapted to rectal or vaginal application to elicit immune responses in rectal, genitourinary, or reproductive mucosa. Finally, vaccine antigens may be adapted to transdermal application in which the skin is lightly scraped and microneedles are used to pierce the outermost layer. In addition to mobilizing the mucosal immune response, this new generation of vaccines may end the anxiety associated with injections and, in turn, improve patient participation.

### Activity

Construct a diagram to illustrate how T cells and B cells differ from each other with respect to the antigens that they bind.

### Think About It

Why is it advantageous to be able to mount a faster immune response upon re-exposure to the same pathogen? How does the immune system accomplish this response?

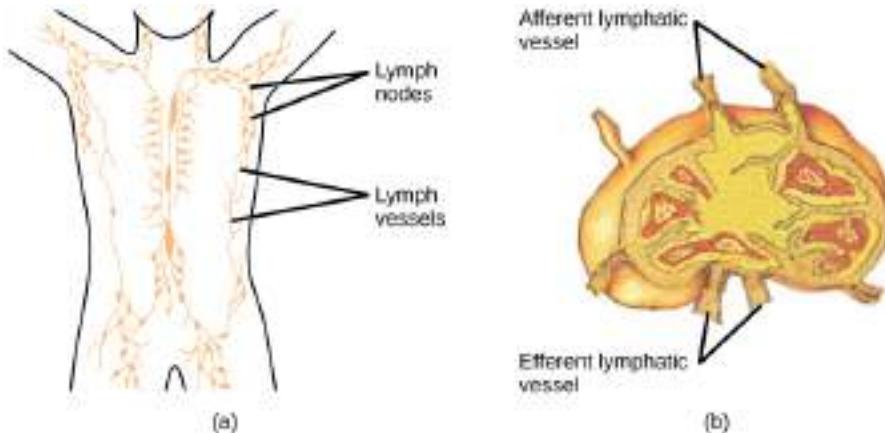

## Primary Centers of the Immune System

Although the immune system is characterized by circulating cells throughout the body, the regulation, maturation, and intercommunication of immune factors occur at specific sites. The blood circulates immune cells, proteins, and other factors through the body. Approximately 0.1 percent of all cells in the blood are leukocytes, which encompass monocytes (the precursor of macrophages) and lymphocytes. The majority of cells in the blood are erythrocytes (red blood cells). **Lymph** is a watery fluid that bathes tissues and organs with protective white blood cells and does not contain erythrocytes. Cells of the immune system can travel between the distinct lymphatic and blood circulatory systems, which are separated by interstitial space, by a process called extravasation (passing through to surrounding tissue).

The cells of the immune system originate from hematopoietic stem cells in the bone marrow. Cytokines stimulate these

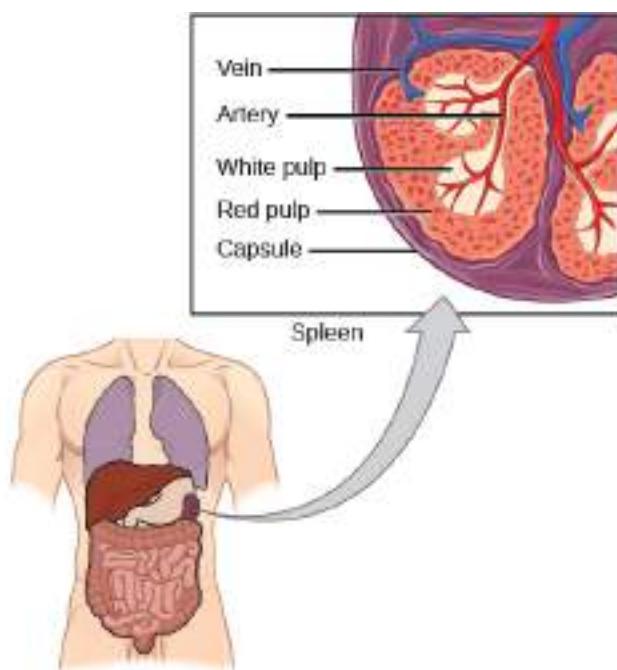

stem cells to differentiate into immune cells. B cell maturation occurs in the bone marrow, whereas naïve T cells transit from the bone marrow to the thymus for maturation. In the thymus, immature T cells that express TCRs complementary to self-antigens are destroyed. This process helps prevent autoimmune responses.

On maturation, T and B lymphocytes circulate to various destinations. Lymph nodes scattered throughout the body, as illustrated in **Figure 33.20**, house large populations of T and B cells, dendritic cells, and macrophages. Lymph gathers antigens as it drains from tissues. These antigens then are filtered through lymph nodes before the lymph is returned to circulation. APCs in the lymph nodes capture and process antigens and inform nearby lymphocytes about potential pathogens.

**Figure 33.20** (a) Lymphatic vessels carry a clear fluid called lymph throughout the body. The liquid enters (b) lymph nodes through afferent vessels. Lymph nodes are filled with lymphocytes that purge infecting cells. The lymph then exits through efferent vessels. (credit: modification of work by NIH, NCI)

The spleen houses B and T cells, macrophages, dendritic cells, and NK cells. The spleen, shown in **Figure 33.21**, is the site where APCs that have trapped foreign particles in the blood can communicate with lymphocytes. Antibodies are synthesized and secreted by activated plasma cells in the spleen, and the spleen filters foreign substances and antibody-complexed pathogens from the blood. Functionally, the spleen is to the blood as lymph nodes are to the lymph.

**Figure 33.21** The spleen is similar to a lymph node but is much larger and filters blood instead of lymph. Blood enters the spleen through arteries and exits through veins. The spleen contains two types of tissue: red pulp and white pulp. Red pulp consists of cavities that store blood. Within the red pulp, damaged red blood cells are removed and replaced by new ones. White pulp is rich in lymphocytes that remove antigen-coated bacteria from the blood. (credit: modification of work by NCI)

## 33.3 | Antibodies

In this section, you will explore the following questions:

- What is cross-reactivity?
- What is the basic structure of an antibody, and what are the functions of antibodies?
- How are antibodies produced?

### Connection for AP<sup>®</sup> Courses

Much of the information in this section is not within the scope for AP<sup>®</sup>. **Antibodies**, also known as immunoglobulins, are proteins produced and secreted by plasma cells (differentiated B lymphocytes) that mediate the humoral immune response. Antibodies are Y-shaped proteins consisting of four polypeptides with at least two binding sites for a specific antigen. The areas where the antigen is recognized on the antibody are variable domains. For AP<sup>®</sup>, you do not need to know the different classes of antibodies or the molecular structure of a specific antibody. What is important to understand is that antibodies are antigen-specific. When antibodies bind antigens, they can neutralize pathogens, mark them for phagocytosis, or activate the complement cascade. Because secreted antibodies can remain in the circulation for many years, secondary exposure to a pathogen results in a faster immune response. Antibodies occur in the blood, in gastric and mucus secretions, and in breast milk, thus providing passive immunity to the infant.

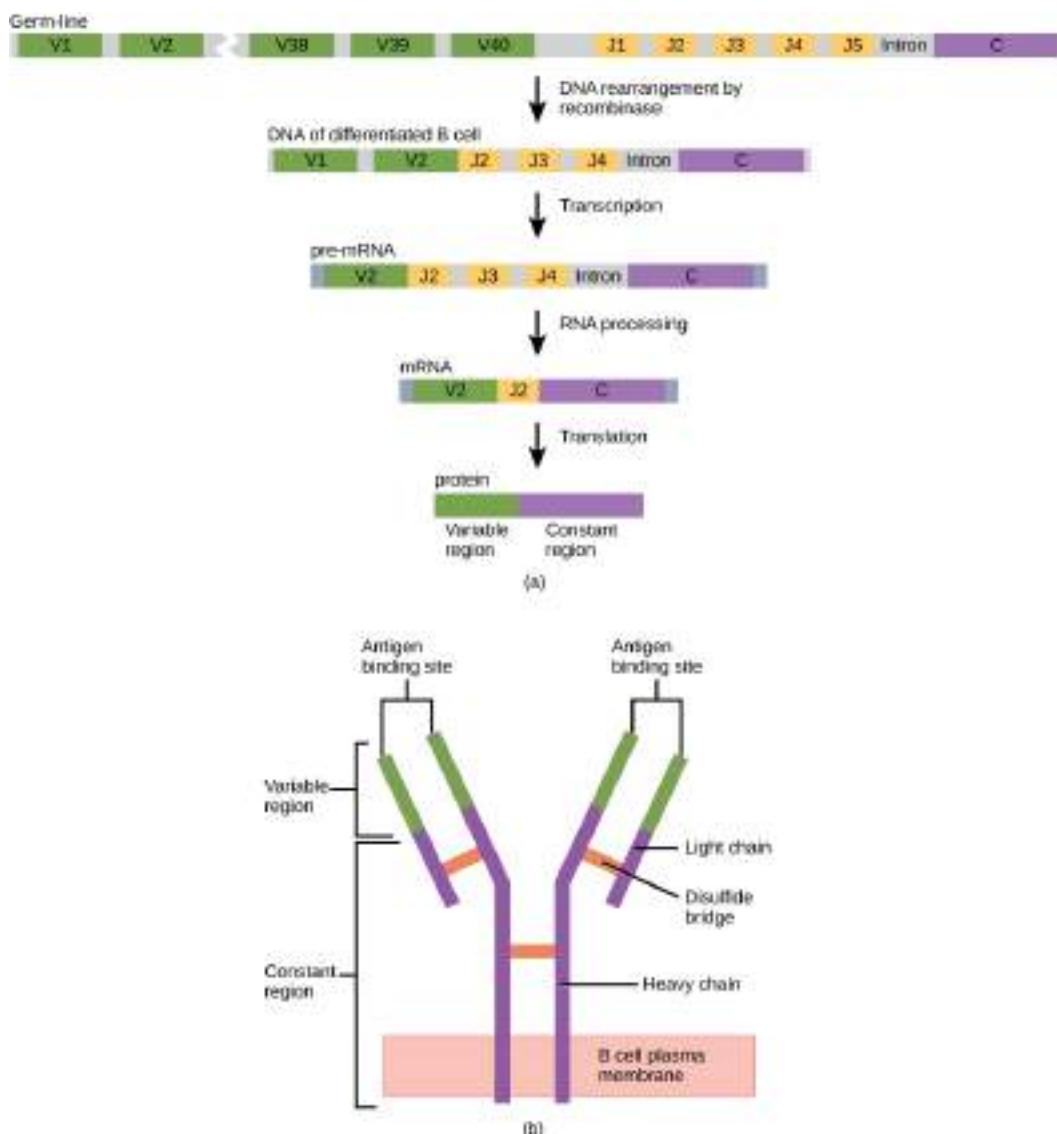

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 and Big Idea 4 of the AP<sup>®</sup> Biology Curriculum Framework. The AP<sup>®</sup> Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

## Antibody Structure

An antibody molecule is comprised of four polypeptides: two identical heavy chains (large peptide units) that are partially bound to each other in a “Y” formation, which are flanked by two identical light chains (small peptide units), as illustrated in **Figure 33.22**. Bonds between the cysteine amino acids in the antibody molecule attach the polypeptides to each other. The areas where the antigen is recognized on the antibody are variable domains and the antibody base is composed of constant domains.

In germ-line B cells, the variable region of the light chain gene has 40 variable (V) and five joining (J) segments. An enzyme called DNA recombinase randomly excises most of these segments out of the gene, and splices one V segment to one J segment. During RNA processing, all but one V and J segment are spliced out. Recombination and splicing may result in over  $10^6$  possible VJ combinations. As a result, each differentiated B cell in the human body typically has a unique variable chain. The constant domain, which does not bind antibody, is the same for all antibodies.

**Figure 33.22** (a) As a germ-line B cell matures, an enzyme called DNA recombinase randomly excises V and J segments from the light chain gene. Splicing at the mRNA level results in further gene rearrangement. As a result, (b) each antibody has a unique variable region capable of binding a different antigen.

Similar to TCRs and BCRs, antibody diversity is produced by the mutation and recombination of approximately 300 different gene segments encoding the light and heavy chain variable domains in precursor cells that are destined to become B cells. The variable domains from the heavy and light chains interact to form the binding site through which an antibody can bind a specific epitope on an antigen. The numbers of repeated constant domains in Ig classes are the same for all antibodies corresponding to a specific class. Antibodies are structurally similar to the extracellular component of the BCRs, and B cell maturation to plasma cells can be visualized in simple terms as the cell acquires the ability to secrete the extracellular portion of its BCR in large quantities.

### Antibody Classes

Antibodies can be divided into five classes—IgM, IgG, IgA, IgD, IgE—based on their physiochemical, structural, and immunological properties. IgGs, which make up about 80 percent of all antibodies, have heavy chains that consist of one variable domain and three identical constant domains. IgA and IgD also have three constant domains per heavy chain, whereas IgM and IgE each have four constant domains per heavy chain. The variable domain determines binding specificity and the constant domain of the heavy chain determines the immunological mechanism of action of the corresponding antibody class. It is possible for two antibodies to have the same binding specificities but be in different classes and, therefore, to be involved in different functions.

After an adaptive defense is produced against a pathogen, typically plasma cells first secrete IgM into the blood. BCRs on

naïve B cells are of the IgM class and occasionally IgD class. IgM molecules make up approximately ten percent of all antibodies. Prior to antibody secretion, plasma cells assemble IgM molecules into pentamers (five individual antibodies) linked by a joining (J) chain, as shown in **Figure 33.23**. The pentamer arrangement means that these macromolecules can bind ten identical antigens. However, IgM molecules released early in the adaptive immune response do not bind to antigens as stably as IgGs, which are one of the possible types of antibodies secreted in large quantities upon re-exposure to the same pathogen. **Figure 33.23** summarizes the properties of immunoglobulins and illustrates their basic structures.

| Name | Properties                                                                                                       | Structure                                                                           |
|------|------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------|
| IgA  | Found in mucus, saliva, tears, and breast milk. Protects against pathogens.                                      |  |
| IgD  | Part of the B cell receptor. Activates basophils and mast cells.                                                 |  |
| IgE  | Protects against parasitic worms. Responsible for allergic reactions.                                            |  |
| IgG  | Secreted by plasma cells in the blood. Able to cross the placenta into the fetus.                                |  |
| IgM  | May be attached to the surface of a B cell or secreted into the blood. Responsible for early stages of immunity. |  |

**Figure 33.23** Immunoglobulins have different functions, but all are composed of light and heavy chains that form a Y-shaped structure.

IgAs populate the saliva, tears, breast milk, and mucus secretions of the gastrointestinal, respiratory, and genitourinary tracts. Collectively, these bodily fluids coat and protect the extensive mucosa (4000 square feet in humans). The total number of IgA molecules in these bodily secretions is greater than the number of IgG molecules in the blood serum. A small amount of IgA is also secreted into the serum in monomeric form. Conversely, some IgM is secreted into bodily fluids of the mucosa. Similar to IgM, IgA molecules are secreted as polymeric structures linked with a J chain. However, IgAs are secreted mostly as dimeric molecules, not pentamers.

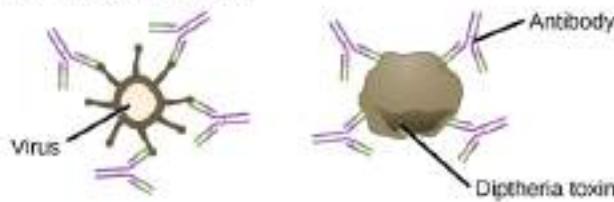

IgE is present in the serum in small quantities and is best characterized in its role as an allergy mediator. IgD is also present in small quantities. Similar to IgM, BCRs of the IgD class are found on the surface of naïve B cells. This class supports antigen recognition and maturation of B cells to plasma cells.

## Antibody Functions

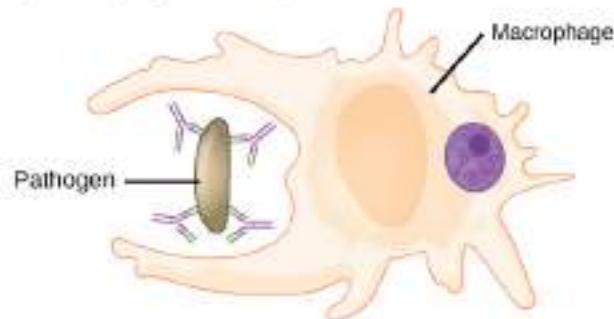

Differentiated plasma cells are crucial players in the humoral response, and the antibodies they secrete are particularly significant against extracellular pathogens and toxins. Antibodies circulate freely and act independently of plasma cells. Antibodies can be transferred from one individual to another to temporarily protect against infectious disease. For instance, a person who has recently produced a successful immune response against a particular disease agent can donate blood to a nonimmune recipient and confer temporary immunity through antibodies in the donor's blood serum. This phenomenon is called **passive immunity**; it also occurs naturally during breastfeeding, which makes breastfed infants highly resistant to infections during the first few months of life.

Antibodies coat extracellular pathogens and neutralize them, as illustrated in **Figure 33.24**, by blocking key sites on the pathogen that enhance their infectivity (such as receptors that "dock" pathogens on host cells). Antibody neutralization can prevent pathogens from entering and infecting host cells, as opposed to the CTL-mediated approach of killing cells that are already infected to prevent progression of an established infection. The neutralized antibody-coated pathogens can then be filtered by the spleen and eliminated in urine or feces.

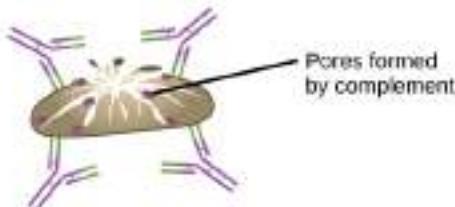

**(a) Neutralization** Antibodies prevent a virus or toxic protein from binding their target.

**(b) Opsonization** A pathogen tagged by antibodies is consumed by a macrophage or neutrophil.

**(c) Complement activation** Antibodies attached to the surface of a pathogen cell activate the complement system.

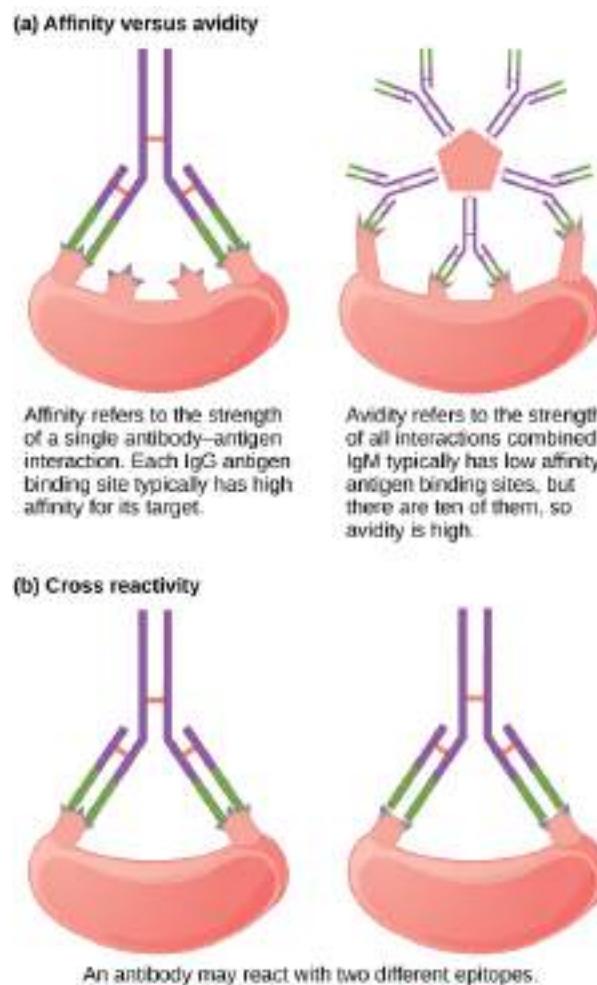

**Figure 33.24** Antibodies may inhibit infection by (a) preventing the antigen from binding its target, (b) tagging a pathogen for destruction by macrophages or neutrophils, or (c) activating the complement cascade.

Antibodies also mark pathogens for destruction by phagocytic cells, such as macrophages or neutrophils, because phagocytic cells are highly attracted to macromolecules complexed with antibodies. Phagocytic enhancement by antibodies is called opsonization. In a process called complement fixation, IgM and IgG in serum bind to antigens and provide docking sites onto which sequential complement proteins can bind. The combination of antibodies and complement enhances opsonization even further and promotes rapid clearing of pathogens.

#### Affinity, Avidity, and Cross Reactivity

Not all antibodies bind with the same strength, specificity, and stability. In fact, antibodies exhibit different **affinities** (attraction) depending on the molecular complementarity between antigen and antibody molecules, as illustrated in **Figure 33.25**. An antibody with a higher affinity for a particular antigen would bind more strongly and stably, and thus would be expected to present a more challenging defense against the pathogen corresponding to the specific antigen.

**Figure 33.25** (a) Affinity refers to the strength of single interaction between antigen and antibody, while avidity refers to the strength of all interactions combined. (b) An antibody may cross react with different epitopes.

The term **avidity** describes binding by antibody classes that are secreted as joined, multivalent structures (such as IgM and IgA). Although avidity measures the strength of binding, just as affinity does, the avidity is not simply the sum of the affinities of the antibodies in a multimeric structure. The avidity depends on the number of identical binding sites on the antigen being detected, as well as other physical and chemical factors. Typically, multimeric antibodies, such as pentameric IgM, are classified as having lower affinity than monomeric antibodies, but high avidity. Essentially, the fact that multimeric antibodies can bind many antigens simultaneously balances their slightly lower binding strength for each antibody/antigen interaction.

Antibodies secreted after binding to one epitope on an antigen may exhibit cross reactivity for the same or similar epitopes on different antigens. Because an epitope corresponds to such a small region (the surface area of about four to six amino acids), it is possible for different macromolecules to exhibit the same molecular identities and orientations over short regions. **Cross reactivity** describes when an antibody binds not to the antigen that elicited its synthesis and secretion, but to a different antigen.

Cross reactivity can be beneficial if an individual develops immunity to several related pathogens despite having only been exposed to or vaccinated against one of them. For instance, antibody cross reactivity may occur against the similar surface structures of various Gram-negative bacteria. Conversely, antibodies raised against pathogenic molecular components that resemble self molecules may incorrectly mark host cells for destruction and cause autoimmune damage. Patients who develop systemic lupus erythematosus (SLE) commonly exhibit antibodies that react with their own DNA. These antibodies may have been initially raised against the nucleic acid of microorganisms but later cross-reacted with self-antigens. This phenomenon is also called molecular mimicry.

## Antibodies of the Mucosal Immune System

Antibodies synthesized by the mucosal immune system include IgA and IgM. Activated B cells differentiate into mucosal

plasma cells that synthesize and secrete dimeric IgA, and to a lesser extent, pentameric IgM. Secreted IgA is abundant in tears, saliva, breast milk, and in secretions of the gastrointestinal and respiratory tracts. Antibody secretion results in a local humoral response at epithelial surfaces and prevents infection of the mucosa by binding and neutralizing pathogens.

## 33.4 | Disruptions in the Immune System

In this section, you will explore the following questions:

- What is hypersensitivity?
- What is autoimmunity, and what is an example of an autoimmune disease?

### Connection for AP<sup>®</sup> Courses

Much of the information in this section is not within the scope for AP<sup>®</sup>. Immune systems can, at times, be defeated by pathogens. For example, some bacteria, including *Streptococcus pneumoniae*, surround themselves with a capsule that inhibits phagocytes from engulfing them and displaying antigens to the adaptive immune system. Human immunodeficiency virus (HIV), the virus that causes AIDS, infects helper T-cells via their CD4 surface molecules, gradually depleting the number of T<sub>H</sub> cells in the body; this inhibits the adaptive immune system's capacity to sufficiently respond to infection or tumors that persons with healthy immune systems can defend against. Allergies to pollen or pet dander occur when the immune system attacks the body's own cells or tissues. Other examples of autoimmune diseases include type I diabetes and ALS. In the rejection of transplanted organs, the immune system is responding to unmatched MHC proteins on the cells of the donated ("non-self") organ. However, the immune system usually responds as it should, defending you against infection and getting you back to your AP<sup>®</sup> Biology class as soon as possible.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 of the AP<sup>®</sup> Biology Curriculum Framework. The AP<sup>®</sup> Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Learning Objective</b>         | <b>2.28</b> The student is able to use representations or models to analyze quantitatively and qualitatively the effects of disruptions to dynamic homeostasis in biological systems. |

### Immunodeficiency

Failures, insufficiencies, or delays at any level of the immune response can allow pathogens or tumor cells to gain a foothold and replicate or proliferate to high enough levels that the immune system becomes overwhelmed. **Immunodeficiency** is the failure, insufficiency, or delay in the response of the immune system, which may be acquired or inherited. Immunodeficiency can be acquired as a result of infection with certain pathogens (such as HIV), chemical exposure (including certain medical treatments), malnutrition, or possibly by extreme stress. For instance, radiation exposure can destroy populations of lymphocytes and elevate an individual's susceptibility to infections and cancer. Dozens of genetic disorders result in immunodeficiencies, including Severe Combined Immunodeficiency (SCID), Bare lymphocyte syndrome, and MHC II deficiencies. Rarely, primary immunodeficiencies that are present from birth may occur. Neutropenia is one form in which the immune system produces a below-average number of neutrophils, the body's most

abundant phagocytes. As a result, bacterial infections may go unrestricted in the blood, causing serious complications.

## everyday CONNECTION for AP<sup>®</sup> Courses

This is a white severe combined immunodeficiency (SCID) mouse. SCID mice are used to study the immune system.

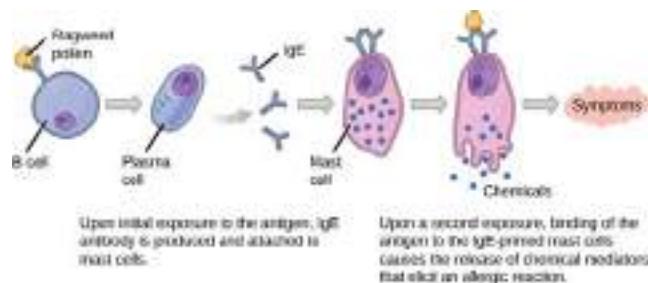

Figure 33.26

## Hypersensitivities

Maladaptive immune responses toward harmless foreign substances or self antigens that occur after tissue sensitization are termed **hypersensitivities**. The types of hypersensitivities include immediate, delayed, and autoimmunity. A large proportion of the population is affected by one or more types of hypersensitivity.

### Allergies

The immune reaction that results from immediate hypersensitivities in which an antibody-mediated immune response occurs within minutes of exposure to a harmless antigen is called an **allergy**. In the United States, 20 percent of the population exhibits symptoms of allergy or asthma, whereas 55 percent test positive against one or more allergens. Upon initial exposure to a potential allergen, an allergic individual synthesizes antibodies of the IgE class via the typical process of APCs presenting processed antigen to T<sub>H</sub> cells that stimulate B cells to produce IgE. This class of antibodies also mediates the immune response to parasitic worms. The constant domain of the IgE molecules interact with mast cells embedded in connective tissues. This process primes, or sensitizes, the tissue. Upon subsequent exposure to the same allergen, IgE molecules on mast cells bind the antigen via their variable domains and stimulate the mast cell to release the modified amino acids histamine and serotonin; these chemical mediators then recruit eosinophils which mediate allergic responses. **Figure 33.27** shows an example of an allergic response to ragweed pollen. The effects of an allergic reaction range from mild symptoms like sneezing and itchy, watery eyes to more severe or even life-threatening reactions involving intensely itchy welts or hives, airway contraction with severe respiratory distress, and plummeting blood pressure. This extreme reaction is known as anaphylactic shock. If not treated with epinephrine to counter the blood pressure and breathing effects, this condition can be fatal.

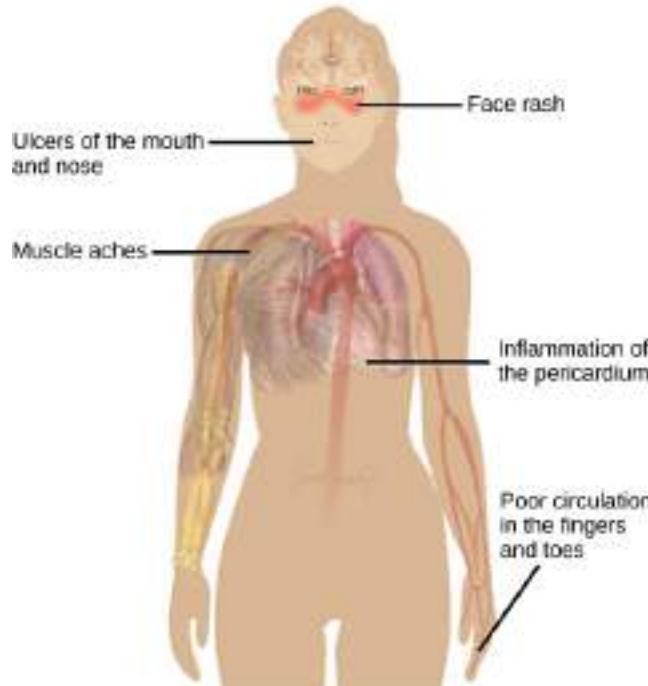

**Figure 33.27** On first exposure to an allergen, an IgE antibody is synthesized by plasma cells in response to a harmless antigen. The IgE molecules bind to mast cells, and on secondary exposure, the mast cells release histamines and other modulators that affect the symptoms of allergy. (credit: modification of work by NIH)

Delayed hypersensitivity is a cell-mediated immune response that takes approximately one to two days after secondary exposure for a maximal reaction to be observed. This type of hypersensitivity involves the  $T_{H}1$  cytokine-mediated inflammatory response and may manifest as local tissue lesions or contact dermatitis (rash or skin irritation). Delayed hypersensitivity occurs in some individuals in response to contact with certain types of jewelry or cosmetics. Delayed hypersensitivity facilitates the immune response to poison ivy and is also the reason why the skin test for tuberculosis results in a small region of inflammation on individuals who were previously exposed to *Mycobacterium tuberculosis*. That is also why cortisone is used to treat such responses: it will inhibit cytokine production.

### Autoimmunity

**Autoimmunity** is a type of hypersensitivity to self antigens that affects approximately five percent of the population. Most types of autoimmunity involve the humoral immune response. Antibodies that inappropriately mark self components as foreign are termed **autoantibodies**. In patients with the autoimmune disease myasthenia gravis, muscle cell receptors that induce contraction in response to acetylcholine are targeted by antibodies. The result is muscle weakness that may include marked difficulty with fine and/or gross motor functions. In systemic lupus erythematosus, a diffuse autoantibody response to the individual's own DNA and proteins results in various systemic diseases. As illustrated in **Figure 33.28**, systemic lupus erythematosus may affect the heart, joints, lungs, skin, kidneys, central nervous system, or other tissues, causing tissue damage via antibody binding, complement recruitment, lysis, and inflammation.

**Figure 33.28** Systemic lupus erythematosus is characterized by autoimmunity to the individual's own DNA and/or proteins, which leads to varied dysfunction of the organs. (credit: modification of work by Mikael Häggström)

Autoimmunity can develop with time, and its causes may be rooted in molecular mimicry. Antibodies and TCRs may bind self antigens that are structurally similar to pathogen antigens, which the immune receptors first raised. As an example,

infection with *Streptococcus pyogenes* (bacterium that causes strep throat) may generate antibodies or T cells that react with heart muscle, which has a similar structure to the surface of *S. pyogenes*. These antibodies can damage heart muscle with autoimmune attacks, leading to rheumatic fever. Insulin-dependent (Type 1) diabetes mellitus arises from a destructive inflammatory T<sub>H</sub>1 response against insulin-producing cells of the pancreas. Patients with this autoimmunity must be injected with insulin that originates from other sources.

## KEY TERMS

**adaptive immunity** immunity that has memory and occurs after exposure to an antigen either from a pathogen or a vaccination

**affinity** attraction of molecular complementarity between antigen and antibody molecules

**allergy** immune reaction that results from immediate hypersensitivities in which an antibody-mediated immune response occurs within minutes of exposure to a harmless antigen

**antibody** protein that is produced by plasma cells after stimulation by an antigen; also known as an immunoglobulin

**antigen** foreign or “non-self” protein that triggers the immune response

**antigen-presenting cell (APC)** immune cell that detects, engulfs, and informs the adaptive immune response about an infection by presenting the processed antigen on the cell surface

**autoantibody** antibody that incorrectly marks “self” components as foreign and stimulates the immune response

**autoimmune response** inappropriate immune response to host cells or self-antigens

**autoimmunity** type of hypersensitivity to self antigens

**avidity** total binding strength of a multivalent antibody with antigen

**B cell** lymphocyte that matures in the bone marrow and differentiates into antibody-secreting plasma cells

**basophil** leukocyte that releases chemicals usually involved in the inflammatory response

**cell-mediated immune response** adaptive immune response that is carried out by T cells

**clonal selection** activation of B cells corresponding to one specific BCR variant and the dramatic proliferation of that variant

**complement system** array of approximately 20 soluble proteins of the innate immune system that enhance phagocytosis, bore holes in pathogens, and recruit lymphocytes; enhances the adaptive response when antibodies are produced

**cross reactivity** binding of an antibody to an epitope corresponding to an antigen that is different from the one the antibody was raised against

**cytokine** chemical messenger that regulates cell differentiation, proliferation, gene expression, and cell trafficking to effect immune responses

**cytotoxic T lymphocyte (CTL)** adaptive immune cell that directly kills infected cells via perforin and granzymes, and releases cytokines to enhance the immune response

**dendritic cell** immune cell that processes antigen material and presents it on the surface of other cells to induce an immune response

**effector cell** lymphocyte that has differentiated, such as a B cell, plasma cell, or cytotoxic T lymphocyte

**eosinophil** leukocyte that responds to parasites and is involved in the allergic response

**epitope** small component of an antigen that is specifically recognized by antibodies, B cells, and T cells; the antigenic determinant

**granzyme** protease that enters target cells through perforin and induces apoptosis in the target cells; used by NK cells and killer T cells

**helper T lymphocyte (T<sub>H</sub>)** cell of the adaptive immune system that binds APCs via MHC II molecules and stimulates B cells or secretes cytokines to initiate the immune response

**host** an organism that is invaded by a pathogen or parasite

**humoral immune response** adaptive immune response that is controlled by activated B cells and antibodies

**hypersensitivities** spectrum of maladaptive immune responses toward harmless foreign particles or self antigens; occurs after tissue sensitization and includes immediate-type (allergy), delayed-type, and autoimmunity

**immune tolerance** acquired ability to prevent an unnecessary or harmful immune response to a detected foreign body known not to cause disease or to self-antigens

**immunodeficiency** failure, insufficiency, or delay at any level of the immune system, which may be acquired or inherited

**inflammation** localized redness, swelling, heat, and pain that results from the movement of leukocytes and fluid through opened capillaries to a site of infection

**innate immunity** immunity that occurs naturally because of genetic factors or physiology, and is not induced by infection or vaccination

**interferon** cytokine that inhibits viral replication and modulates the immune response

**lymph** watery fluid that bathes tissues and organs with protective white blood cells and does not contain erythrocytes

**lymphocyte** leukocyte that is histologically identifiable by its large nuclei; it is a small cell with very little cytoplasm

**macrophage** large phagocytic cell that engulfs foreign particles and pathogens

**major histocompatibility class (MHC) I/II molecule** protein found on the surface of all nucleated cells (I) or specifically on antigen-presenting cells (II) that signals to immune cells whether the cell is healthy/normal or is infected/cancerous; it provides the appropriate template into which antigens can be loaded for recognition by lymphocytes

**mast cell** leukocyte that produces inflammatory molecules, such as histamine, in response to large pathogens and allergens

**memory cell** antigen-specific B or T lymphocyte that does not differentiate into effector cells during the primary immune response but that can immediately become an effector cell upon re-exposure to the same pathogen

**monocyte** type of white blood cell that circulates in the blood and lymph and differentiates into macrophages after it moves into infected tissue

**mucosa-associated lymphoid tissue (MALT)** collection of lymphatic tissue that combines with epithelial tissue lining the mucosa throughout the body

**natural killer (NK) cell** lymphocyte that can kill cells infected with viruses or tumor cells

**neutrophil** phagocytic leukocyte that engulfs and digests pathogens

**opsonization** process that enhances phagocytosis using proteins to indicate the presence of a pathogen to phagocytic cells

**passive immunity** transfer of antibodies from one individual to another to provide temporary protection against pathogens

**pathogen** an agent, usually a microorganism, that causes disease in the organisms that they invade

**pathogen-associated molecular pattern (PAMP)** carbohydrate, polypeptide, and nucleic acid “signature” that is expressed by viruses, bacteria, and parasites but differs from molecules on host cells

**pattern recognition receptor (PRR)** molecule on macrophages and dendritic cells that binds molecular signatures of pathogens and promotes pathogen engulfment and destruction

**perforin** destructive protein that creates a pore in the target cell; used by NK cells and killer T cells

**plasma cell** immune cell that secretes antibodies; these cells arise from B cells that were stimulated by antigens

**regulatory T ( $T_{reg}$ ) cell** specialized lymphocyte that suppresses local inflammation and inhibits the secretion of cytokines, antibodies, and other stimulatory immune factors; involved in immune tolerance

**T cell** lymphocyte that matures in the thymus gland; one of the main cells involved in the adaptive immune system

## CHAPTER SUMMARY

### 33.1 Innate Immune Response

The innate immune system serves as a first responder to pathogenic threats that bypass natural physical and chemical barriers of the body. Using a combination of cellular and molecular attacks, the innate immune system identifies the nature of a pathogen and responds with inflammation, phagocytosis, cytokine release, destruction by NK cells, and/or a complement system. When innate mechanisms are insufficient to clear an infection, the adaptive immune response is informed and mobilized.

### 33.2 Adaptive Immune Response

The adaptive immune response is a slower-acting, longer-lasting, and more specific response than the innate response. However, the adaptive response requires information from the innate immune system to function. APCs display antigens via MHC molecules to complementary naïve T cells. In response, the T cells differentiate and proliferate, becoming  $T_H$  cells or CTLs.  $T_H$  cells stimulate B cells that have engulfed and presented pathogen-derived antigens. B cells differentiate into plasma cells that secrete antibodies, whereas CTLs induce apoptosis in intracellularly infected or cancerous cells. Memory cells persist after a primary exposure to a pathogen. If re-exposure occurs, memory cells differentiate into effector cells without input from the innate immune system. The mucosal immune system is largely independent from the systemic immune system but functions in a parallel fashion to protect the extensive mucosal surfaces of the body.

### 33.3 Antibodies

Antibodies (immunoglobulins) are the molecules secreted from plasma cells that mediate the humoral immune response. There are five antibody classes; an antibody's class determines its mechanism of action and production site but does not control its binding specificity. Antibodies bind antigens via variable domains and can either neutralize pathogens or mark them for phagocytosis or activate the complement cascade.

### 33.4 Disruptions in the Immune System

Immune disruptions may involve insufficient immune responses or inappropriate immune targets. Immunodeficiency increases an individual's susceptibility to infections and cancers. Hypersensitivities are misdirected responses either to harmless foreign particles, as in the case of allergies, or to host factors, as in the case of autoimmunity. Reactions to self components may be the result of molecular mimicry.

## REVIEW QUESTIONS

1. What is the mechanism that skin uses to protect against diseases caused by organisms?
  - a. high pH
  - b. mucus
  - c. tears
  - d. desiccation
2. How does the human body use a chemical barrier as part of the innate immune response?
3. Which of the following produces an immediate innate immune response by recognizing an invading pathogen and engulfing it?
  - a. Mucus secretions trap and rinse pathogens out of the body.
  - b. Urination carries pathogens out of the urinary tract.
  - c. Low pH conditions in the stomach kill some pathogens and prevent other pathogens from growing.
  - d. Cilia in the nasal passages and respiratory tract push mucus containing trapped pathogens out of the body.

- a. macrophage
  - b. cytokine
  - c. inflammation
  - d. antibody
- 4. How does inflammation develop?**
- a. Inflammation is induced by molecules such as cytokines and histamine that are produced by various host cells in response to pathogens at the site of injury or infection.
  - b. During inflammation, all blood cells retreat from the site of infection in order to protect the circulatory system from pathogen infection.
  - c. Inflammation is an ongoing condition in the human body, part of the way that the innate immune system can respond immediately to an infection.
  - d. When an infection occurs, an immediate inflammatory response occurs as soon as pathogens enter the body.
- 5. Which innate immune system component uses major histocompatibility class (MHC) I molecules directly in its defense strategy?**
- a. macrophages
  - b. neutrophils
  - c. natural killer cells
  - d. interferon
- 6. What is the difference between natural killer cells and macrophages?**
- a. Natural killer cells are not always present in the body and must be induced, whereas macrophages are constantly present.
  - b. Natural killer cells actually kill foreign cells, whereas macrophages serve only a signaling function.
  - c. Only macrophages can invade host tissues to fight foreign cells that make their way into those tissues.
  - d. Natural killer cells kill foreign cells through the processes of lysis and proteolysis, whereas macrophages kill foreign cells by phagocytosis.
- 7. What is the composition of major histocompatibility class (MHC) I molecules?**
- a. lipids
  - b. nucleic acids
  - c. carbohydrates
  - d. proteins
- 8. What is the function of major histocompatibility class (MHC) I molecules?**
- a. MHC I molecules assist with strengthening the cell membrane.
  - b. MHC I molecules present antigens on the surface of a cell.
  - c. MHC I molecules allow movement of materials across the cell membrane.
  - d. MHC I molecules provide signals for processes involved in cell division.
- 9. What is the complement system?**
- a. The complement system contains macrophages that phagocytize foreign pathogens.
  - b. The complement system monitors MHC I molecules on cells and destroys any cell that displays an antigen belonging to a pathogen.
  - c. The complement system contains a group of about 20 proteins in the blood that attack pathogens in a cascading fashion to mark and destroy them.
  - d. The complement system is made up of antibodies specific to each pathogen that are synthesized when a pathogen enters the body.
- 10. Which of the following occurs more rapidly as the result of activation of the complement system?**
- a. pathogen invasion
  - b. pathogen detection
  - c. pathogen reproduction
  - d. pathogen engulfment
- 11. What is another term for adaptive immunity?**
- a. acquired immunity
  - b. innate immunity
  - c. passive immunity
  - d. humoral immunity
- 12. How does adaptive immunity work?**
- a. A person is born having a specific immune responses against any pathogen that the body is exposed to.
  - b. A person is born with the ability to develop a specific immune response against any pathogen within minutes of being exposed to that pathogen.
  - c. A person does not have any immune response against a pathogen, but develops a temporary specific response to that pathogen that is then forgotten.
  - d. A person does not have specific immune response against a pathogen, but develops a specific response to that pathogen that is rapidly recalled later if infection by the same pathogen occurs again.

**13.** What component of the innate immune system is not part of the adaptive immune system?

- a. T cells
- b. antibodies
- c. mast cells
- d. B cells

**14.** What is the difference between innate and adaptive immune responses?

- a. The adaptive immune system is faster-acting than the innate immune system.
- b. The adaptive immune system produces a longer-lasting defense than the innate immune system.
- c. The innate immune system produces a more specific defense than the adaptive immune system.
- d. The innate immune system has a more sophisticated memory than the adaptive immune system.

**15.** Which cells are unique to the humoral immune response?

- a. cytotoxic T cells
- b. antigen-presenting cells
- c. helper T cells
- d. B cells

**16.** How does the humoral immune response operate?

- a. The humoral immune response primarily targets infected host cells to destroy them before the infecting pathogen can reproduce.
- b. The humoral immune response produces antibodies that are specifically targeted against each pathogen.
- c. The humoral immune response produces cytotoxic T cells that induce apoptosis in pathogen-infected cells.
- d. The humoral immune response is the only system that involves memory cells that are able to respond later to a pathogen that has invaded the body at an earlier time.

**17.** An antibody sometimes binds to an antigen other than the antigen that elicited its synthesis. What term refers to this behavior?

- a. avidity
- b. cross reactivity
- c. hypersensitivity
- d. affinity

**18.** A biologist runs some tests and observes that the same antibody binds to several different proteins. Why might this occur?

- a. The antibody is showing that it has high affinity for antigens.
- b. The antibody is showing that it has high avidity for antigens.
- c. The antibody is showing cross reactivity to the antigens.
- d. The antibody is showing hypersensitivity to the antigens.

**19.** How many and what types of polypeptides make up an antibody molecule?

- a. One heavy polypeptide chain and one light polypeptide chain
- b. Two heavy polypeptide chains and one light polypeptide chain
- c. Two heavy polypeptide chains and two light polypeptide chains
- d. One heavy polypeptide chain and two light polypeptide chains

**20.** Why do antibodies isolated from the same individual show a variety of constant domains?

- a. The antibodies were synthesized in response to infections by different pathogens.
- b. The antibodies were transmitted as the result of passive immunity.
- c. The antibodies have different specificities of antigen binding.
- d. The antibodies belong to different classes of immunoglobulin molecules.

**21.** What enzyme is responsible for the random excision of variable gene segments making up an antibody light chain in DNA?

- a. DNA polymerase
- b. DNA recombinase
- c. DNA ligase
- d. DNA helicase

**22.** How are antibodies produced in a B cell?

- a. RNA processing → DNA rearrangement → transcription → translation → mature antibody
- b. Transcription → RNA processing → DNA rearrangement → translation → mature antibody
- c. DNA rearrangement → RNA processing → transcription → translation → mature antibody
- d. DNA rearrangement → transcription → RNA processing → translation → mature antibody

**23.** What is a definition of hypersensitivity?

- a. maladaptive immune responses to otherwise harmless proteins
- b. measure of the attraction between an antigen and an antibody
- c. total binding strength of a multivalent antibody with an antigen
- d. binding of an antibody to an antigen different from the one that elicited its synthesis
- 24.** An allergy has been described as a non-protective immune response. Which statement provides information supporting this description?
- An allergic response occurs when B cells produce IgE molecules in response to a foreign protein, which causes histamine to be released.
  - An allergy results from an immune response to a protein that does not cause harm and that the body needs no defense against.
  - People with allergies develop unpleasant symptoms such as watery, itchy eyes, swollen tissues, and sneezing.
  - When their blood is tested, people with allergies show that they have antibodies that bind to one or more foreign proteins.
- 25.** What is the term for antibodies that inappropriately mark self components as foreign?
- cross reactive
  - epitopes
  - allergens
  - autoantibodies

## CRITICAL THINKING QUESTIONS

- 29.** Why does the human body need more than its skin to function as a barrier to infecting pathogens?
- Skin works only against some types of bacteria. To prevent the entry of other pathogens, other physical or chemical barriers are needed.
  - Skin does not provide a broad coverage against invasion of the body by any foreign particle, so it is not a very effective barrier.
  - Pathogens could enter the body through several places that are not covered by skin that need to have a barrier to prevent infection.
  - Skin acts only as a chemical barrier against pathogens. The body also needs physical barriers to prevent various types of infection.

- 30.** Cell surface recognition occurs during many types of immune responses, including immediate and induced immune responses. How do natural killer cells and interferons represent one of each type of immune response (immediate and induced), and how does cell surface

**26.** Why do some people with type 1 diabetes develop the disease as the result of an immune response?

- Their B cells produced IgE molecules in response to a harmless protein, which caused histamine to be released.
- Their B cells responded to a self protein to produce autoantibodies, which elicited inflammation that caused organ damage.
- They had a delayed response to a harmful protein that entered the body and activated both the innate and adaptive immune systems.
- They acquired antibodies to insulin through passive immunity, and these antibodies bind to insulin whenever it is produced in the body.

**27.** What are the three types of hypersensitivity?

- innate, acquired, and immunodeficiency
- variable, constant, and recombinant
- immediate, delayed, and autoimmunity
- active, passive, and adaptive

**28.** What is the definition of autoimmunity?

- binding of an antibody to a viral antigen
- immune response to self antigens
- maladaptive immune response to harmless foreign proteins
- failure to mount an immune response

recognition play a role?

- a. Natural killer cells are an example of induced immune response as they attack host cells that have lost normal cell surface markers. Interferons are an example of immediate immune response as they are induced after cell surface markers on invading pathogens are recognized by host cells.
- b. Natural killer cells are an example of immediate immune response as they attack host cells that have lost normal cell surface markers. Interferons are an example of induced immune response as they are induced after cell surface markers on invading pathogens are recognized by host cells.
- c. Natural killer cells are an example of immediate immune response as they are induced after cell surface markers on invading pathogens are recognized by host cells. Interferons are an example of induced immune response as they attack host cells that have lost normal cell surface markers.
- d. Natural killer cells are an example of induced immune response as they are induced after cell surface markers on invading pathogens are recognized by host cells. Interferons are an example of immediate immune response as they attack host cells that have lost normal cell surface markers.
- 31.** Why might different MHC I molecules between donor and recipient cells lead to rejection of a transplanted organ or tissue?
- a. The natural killer cells in the recipient will identify the MHC I molecules on transplanted organ as non-self proteins, causing lysis of transplanted cells. Other host cells will join to phagocytize the foreign cells.
- b. The neutrophils in the recipient will identify the MHC I molecules on transplanted organ as non-self proteins, causing lysis of transplanted cells. Other host cells will join to phagocytize the foreign cells.
- c. B lymphocytes in the recipient will identify the MHC I molecules on transplanted organ as non-self proteins. The foreign cells will then be engulfed and destroyed by B lymphocytes.
- d. The macrophages in the recipient will identify the MHC I molecules on transplanted organ as non-self proteins, causing lysis of transplanted cells. Other host cells will join to phagocytize the foreign cells.
- 32.** Suppose a person was born without the ability to produce MHC I molecules. What problem would that create?
- a. A person without the ability to produce MHC I molecules would die immediately.
- b. A person without the ability to produce MHC I molecules would recognize self as non-self, resulting in autoimmune disease.
- c. The person's immune system would not be able to distinguish self and non-self. This would make the person very vulnerable to infection.
- d. The person's immune system would not be able to destroy foreign pathogen due to lack of hydrolytic enzymes. This would make the person very vulnerable to infection.
- 33.** Suppose a series of genetic mutations prevented some, but not all, of the complement proteins from binding antibodies or pathogens. Would the entire complement system be compromised? Why or why not?
- a. No, because the complement system functions as a cascade, with each protein triggering the activity of the next protein in the cascade.
- b. Yes, because the complement system functions as a cascade, with each protein triggering the activity of the next protein in the cascade.
- c. Yes, because all the proteins of the complement system function independently.
- d. No, because all the proteins of the complement system function independently.
- 34.** What is a likely reason to explain why vertebrate animals evolved an adaptive immune system rather than an innate system involving specific responses to specific pathogens?
- a. An adaptive immune system requires an immense amount of information to be stored, which allows vertebrate cells to be able to mount specific responses to every pathogen.
- b. As new pathogens evolve all the time, it is more conservative of energy and information storage to have an adaptive immune system that can respond to same pathogens in different ways.
- c. As new pathogens evolve all the time, it is more conservative of energy and information storage to have an adaptive immune system that can respond to different pathogens in a specific way.
- d. As new pathogens evolve all the time, it is more conservative of energy and information storage to have an adaptive immune system that can respond to different pathogens in a non-specific way.
- 35.** Invertebrate animals have innate immune systems but lack adaptive immune systems. Vertebrates, including fish, amphibians, reptiles, birds, and mammals have both systems. What does this suggest about the evolution of these two immune systems?

- a. This suggests that the innate immune system evolved first. Invertebrates and vertebrates had a common ancestor, which had an innate immune system. After the two lineages diverged, the vertebrate line developed adaptive immunity, which continued to evolve in all vertebrates.
- b. This suggests that the adaptive immune system evolved first. Invertebrates and vertebrates had a common ancestor, which had an innate immune system. After the two lineages diverged, the vertebrate line developed adaptive immunity, which continued to evolve in all vertebrates.
- c. This suggests that the innate immune system evolved first. Invertebrates and vertebrates had a common ancestor, which had an adaptive immune system. After the two lineages diverged, the vertebrate line developed innate immunity, which continued to evolve in all vertebrates.
- d. This suggests that the adaptive immune system evolved first. Invertebrates and vertebrates had a common ancestor, which had an adaptive immune system. After the two lineages diverged, the vertebrate line developed innate immunity, which continued to evolve in all vertebrates.
- 36.** What are naïve B or T cells and how do they function in cell-mediated and humoral immune responses?
- a. Naïve B and T cells are lymphocytes of the B and T types that have come into contact with pathogenic antigens. Naïve T cells produce antibodies in the humoral immune response, while naïve B cells stimulate the cell-mediated immune response.
- b. Naïve B and T cells are lymphocytes of the B and T types that normally circulate in the body at all times and have not come into contact with any pathogenic antigens. Activated T cells produce antibodies in the humoral immune response, while activated B cells stimulate the cell-mediated immune response.
- c. Naïve B and T cells are lymphocytes of the B and T types that normally circulate in the body at all times and have not come into contact with any pathogenic antigens. Activated B cells produce antibodies in the humoral immune response, while activated T cells stimulate the cell-mediated immune response.
- d. Naïve B and T cells are lymphocytes of the B and T types that have come into contact with pathogenic antigens. Naïve B cells produce antibodies in the humoral immune response, while naïve T cells stimulate the cell-mediated immune response.
- 37.** A person given a flu vaccine in November comes down with a severe case of influenza in January. What can you conclude about the flu vaccine and cross reactivity?
- a. The flu vaccine elicited antibodies in the person's body that were specific to a particular flu virus. Unfortunately, the flu virus that infected the person later in January was different enough for cross reactivity to occur between the virus antigens causing the infection.
- b. The flu vaccine suppresses antibodies in the person's body that were specific to a particular flu virus. Unfortunately, the flu virus that infected the person later in January was different enough for cross reactivity to occur between the virus antigens causing the infection.
- c. The flu vaccine suppresses antibodies in the person's body that were specific to a particular flu virus. Unfortunately, the flu virus that infected the person later in January was similar enough for cross reactivity to occur between the virus antigens causing the infection.
- d. The flu vaccine suppresses antibodies in the person's body that were specific to a particular flu virus. Unfortunately, the flu virus that infected the person later in January was similar enough for cross reactivity to occur between the virus antigens causing the infection.
- 38.** What function does the diversity of the variable region of an antibody help it perform?
- a. It helps in communication of antibodies with other components of immune system.
- b. It helps the antibodies to function with very low affinity and specificity.
- c. It enables many different antibodies to be made that all have different specificities of binding.
- d. It enables many different antibodies to be made that all have same specificities of binding.
- 39.** How can you explain that the same antibodies found in an infant's body are also present in the infant's mother?
- a. Antibodies produced in the mother's body are passed to the infant via passive immunity through breast milk.
- b. Antibodies produced in the mother's body are passed to the infant via active immunity through breast milk.
- c. Antibodies produced in the mother's body are passed to the infant via passive immunity through the placenta.
- d. Antibodies produced in the infant's body are passed to the mother through the placenta.
- 40.** Researchers have been working on developing methods for stimulating the human immune system to recognize foreign proteins as self proteins. Why would this research be applicable to treating allergies?

- a. In an allergy, a person's immune system has been compromised, which causes unpleasant symptoms.
- b. In an allergy, a person's immune system reacts to its own proteins, which causes unpleasant symptoms.
- c. In an allergy, a person's immune system reacts to a harmless protein from the environment, which causes unpleasant symptoms.
- d. In an allergy, a person's immune system reacts to a harmless protein from the environment, which causes pleasant symptoms.

**41.** A patient has just been informed that they have an autoimmune disease that attacks the salivary glands. How would you explain to the patient what is happening inside their body?

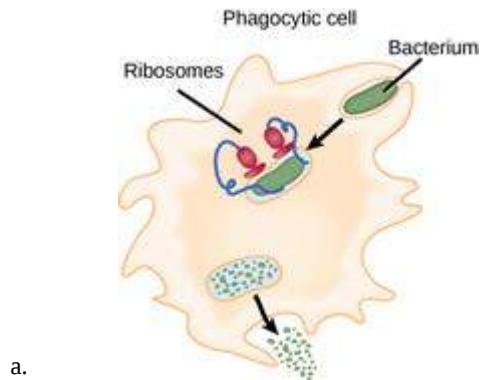

- a. The immune system is producing antibodies against their own proteins present in their salivary glands, causing the salivary glands to break down and become non-functional.
- b. The ability of the immune system to fight the antigen present in the salivary glands might have been compromised, causing the salivary glands to break down and become non-functional.
- c. The immune system might have reacted in an abnormal way to an antigen that may have entered salivary glands, causing the salivary glands to break down and become non-functional.
- d. Some pathogen might have entered the salivary glands, causing the salivary glands to break down and become non-functional.

**42.** An allergic response sometimes leads to a person's death. How can you explain this?

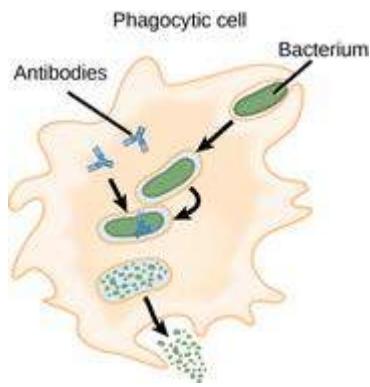

- a. The allergen may bind to the hemoglobin, decreasing the affinity of hemoglobin for oxygen, leading to death.
- b. If a person has a very strong and fast response to an allergen, the tissues in the throat can swell so much in a very short time that the person cannot breathe and blood pressure may increase very quickly. Oxygen will not be carried to the brain and the person may die.
- c. If a person has a very strong and fast response to an allergen, the tissues in the throat can swell so much in a very short time that the person cannot breathe and blood pressure may drop very quickly. Oxygen will reach the cells at a faster rate and the person may die.
- d. If a person has a very strong and fast response to an allergen, the tissues in the throat can swell so much in a very short time that the person cannot breathe and blood pressure may drop very quickly. Oxygen will not be carried to the brain and the person may die.

## TEST PREP FOR AP® COURSES

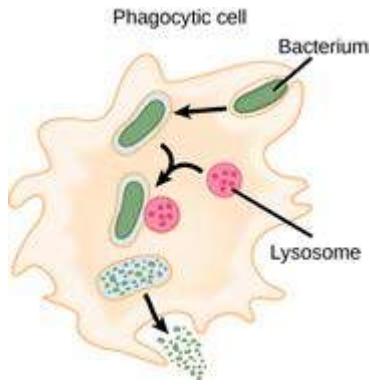

**43.** A pathogenic bacterium has been engulfed by a phagocytic cell as part of the innate immune response. Which of the following illustrations best represents the response? [source: AP Biology Course and Exam Description Fall 2012, p. 132]

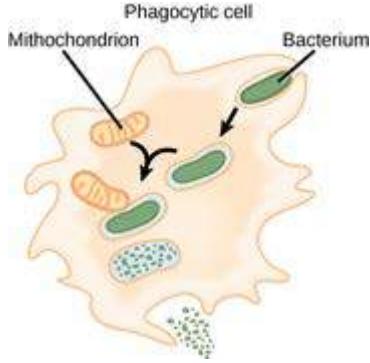

a.

b.

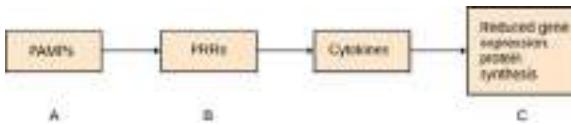

c.

d.

- 44.** How do natural killer cells react to healthy cells compared to cells infected with a pathogen?

- Natural killer cells recognize MHC I on a healthy cell and do not kill it, while the infected cells that do not present MHC I are killed.
- Natural killer cells recognize MHC I on an infected cell and kill it, while the healthy cells that do not present MHC I are not killed.
- Natural killer cells recognize MHC II on a healthy cell and do not kill it, while the infected cells that do not present MHC II are killed.
- Natural killer cells recognize MHC II on an infected cell and kill it, while the healthy cells that do not present MHC II are not killed.

**45.**

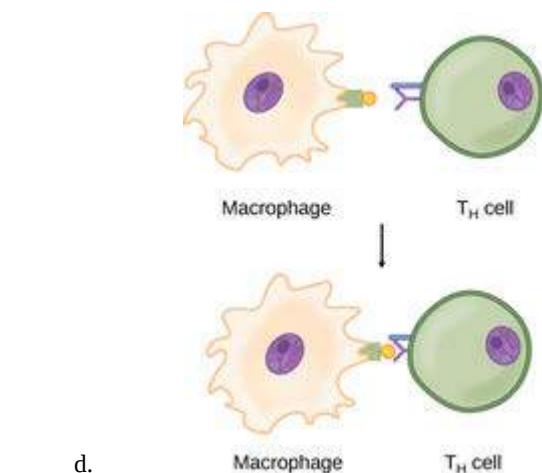

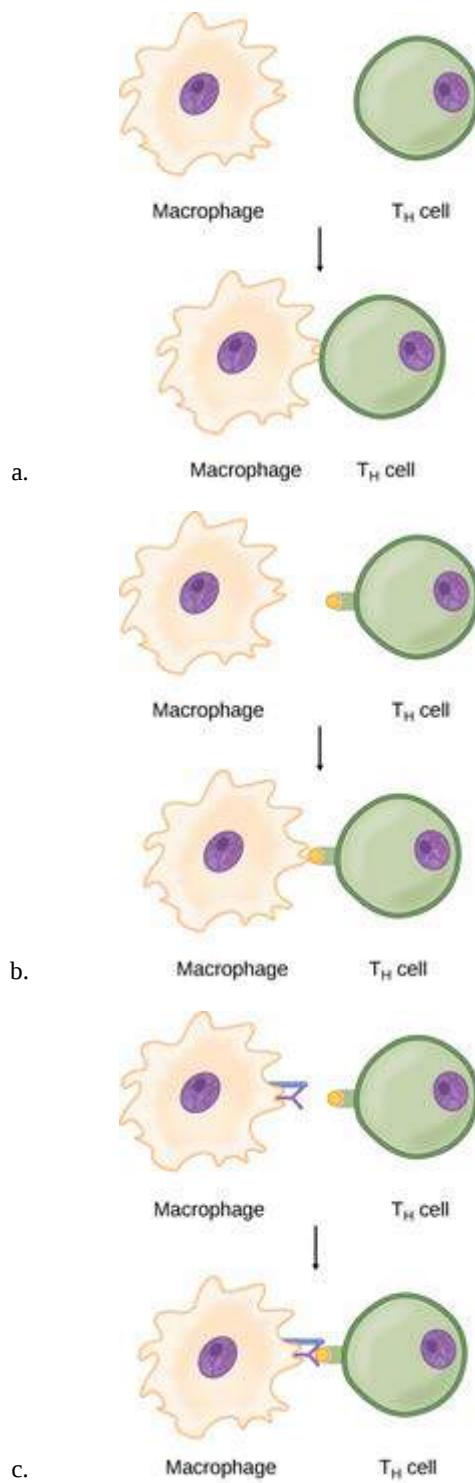

The following incomplete diagram represents a series of events during an innate immune response. The labels A, B, and C need to be replaced with the names of the cells involved. Which set of cells correctly completes this diagram?

- A = infected host cell, B = pathogen, C = healthy host cell
- A = healthy host cell, B = pathogen, C = dendritic cell
- A = dendritic cell, B = infected host cell, C = pathogen
- A = pathogen, B = dendritic cell, C = healthy host cell

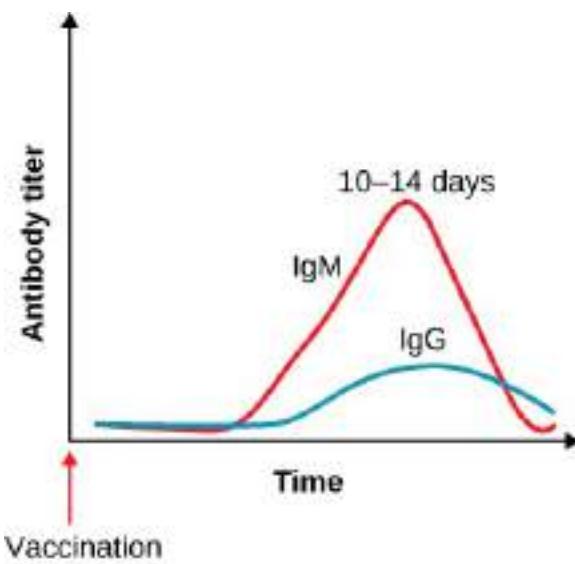

- 46.** A healthy person produces antibodies to pathogens that invade the body. However, if this person becomes infected with HIV, the body loses the ability to produce antibodies. Research has shown that the virus attacks and destroys CD4+T cells. Why does destruction of CD4+T cells lead to a loss of antibody synthesis in HIV-infected patients?

- CD4+T cells are a required intermediate in a series of cell-to-cell signaling events that must be completed before B cells can mature.
- CD4+T cells have CD4 molecules covalently bound to their cell surfaces and do not induce apoptosis in other cells during an immune response.
- CD4+T cell counts are about 1,000 per microliter in a healthy person, but drop below 400 per microliter in a person who cannot mount an immune response.
- CD4+T cell precursors are formed in the bone marrow and then migrate to the thymus, where they develop their T cell receptors.

- 47.** Which of the following diagrams best illustrates how a macrophage activates a helper T cell (THcell)?

48.

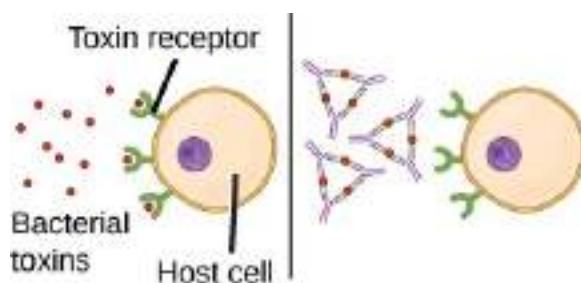

The graph shows changes in a person's blood after they receive a vaccination. Explain how cell communication is involved in bringing about the changes depicted in the graph.

- The vaccine introduces antigens specific to a pathogen into the person's blood. These antigens are moved to the cell surface of antigen-presenting cells present in the blood. Receptors on helper T cells bind to the antigens present on the antigen-presenting cell. This direct cell-to-cell contact initiates a series of events that leads to production of antibodies by B lymphocytes.
- The vaccine introduces antigens specific to a pathogen into the person's blood. These antigens bind to the receptors on the surface of T cells. This direct cell-to-cell contact initiates a series of events that leads to production of antibodies by B lymphocytes.
- The vaccine introduces antigens specific to a pathogen into the person's blood. These antigens are moved to the cell surface of antigen-presenting cells present in the blood. This direct cell-to-cell contact initiates a series of events that leads to production of antibodies by B lymphocytes.
- The vaccine introduces antigens specific to a pathogen into the person's blood. These antigens are moved to the cell surface of antigen-presenting cells present in the blood. Receptors on helper T cells bind to the antigens present on the antigen-presenting cell. This direct cell-to-cell contact initiates a series of events that activates the complement system.

**49.** B cells are important immune cells that fight infections. How is a naïve B cell stimulated to mature into a plasma cell that secretes antibodies?

- T cells secrete cytokines, which help the B cell to multiply and mature into an antibody-producing plasma cell.
- Natural killer cells secrete cytokines, which help the B cell to multiply and mature into an antibody-producing plasma cell.
- T cells secrete interferons, which help the B cell to multiply and mature into an antibody-producing plasma cell.
- Natural killer cells secrete interferons, which help the B cell to multiply and mature into an antibody-producing plasma cell.

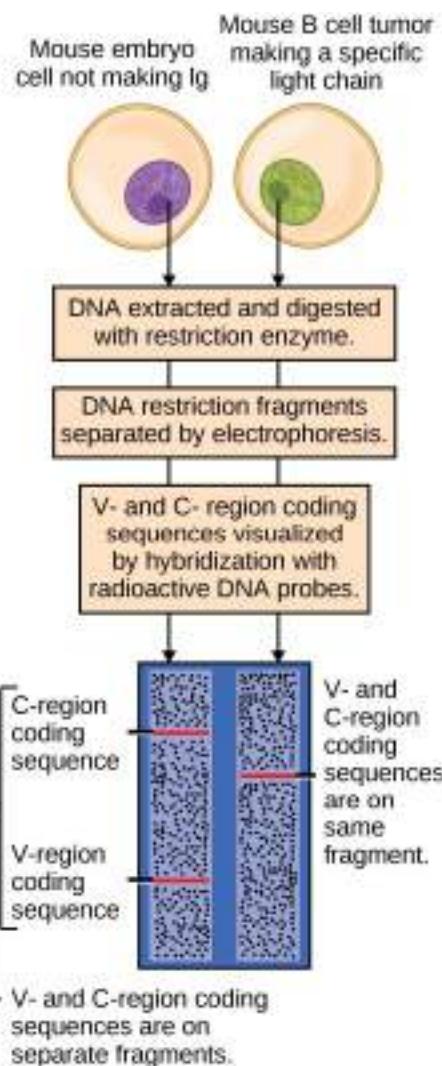

**50.**

The diagram illustrates a process taking place during an immune response. What process is represented by this diagram?

- opsonization
- apoptosis
- neutralization
- complement activation

**51.**

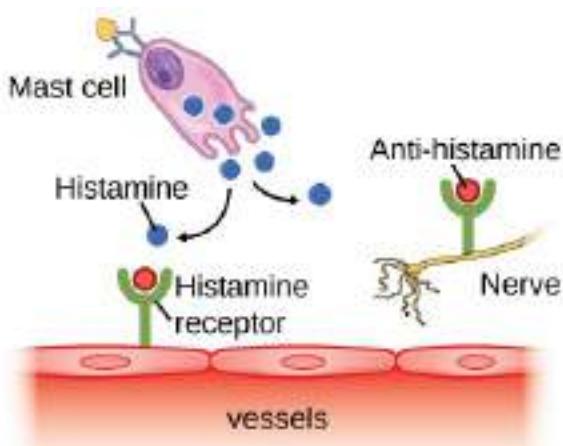

Scientists performed an experiment using a cell from a mouse embryo and a B cell from an adult mouse. The mouse embryo cell does not make antibodies, yet its DNA contains nucleotide sequences encoding antibody polypeptides. The adult mouse B cell makes and secretes a single type of antibody. In the experiment, radiolabeled DNA probes were synthesized to be complementary to the DNA encoding the light chains of antibody produced by the adult mouse B cells. Then, DNA from the mouse embryo cell and from the adult B cell were isolated and tested to see if either hybridized with the synthesized radiolabeled DNA probes. The results are shown in the

diagram. Which claim is best supported by the data?

- The mouse genome contains an enormous number of antibody genes, which accounts for the huge diversity of antibody molecules that can be made.
  - Rearrangement of gene segments encoding antibody polypeptides occurs at the level of DNA to produce an enormous diversity of antibody molecules.
  - The tremendous diversity of antibody molecules that can be made results from post-translational modifications of antibody polypeptide chains.
  - Each antibody is encoded by its own unique gene in the DNA, which explains how antibodies can have different antigen binding properties.
52. How does an antibody molecule bind specifically to one antigen but not to others?
- due to the presence of a specific antigen binding site
  - due to the constant region
  - due to diversity of variable region
  - due to the complete antibody structure
53. The human genome contains less than 50,000 genes, yet a human has the capability of producing more than  $10^{12}$  different antibody molecules. How can this evidence be used to support the claim that the human body has an immune system that is both effective and efficient?
- There are so many different antibody molecules that can be made, each of which can specifically target a particular pathogen to destroy it. This specificity makes the immune system more effective. The immune system is also efficient because each antibody need to have its own gene.
  - There are so many different antibody molecules that can be made, each of which can non-specifically target a particular pathogen to destroy it. This non-specificity makes the immune system more effective. The immune system is also efficient because each antibody does not need to have its own gene.
  - There are so many different antibody molecules that can be made, each of which can specifically target a particular pathogen to destroy it. This specificity makes the immune system more effective. The immune system is also effective because each antibody does not need to have its own gene.
  - There are so many different antibody molecules that can be made, each of which can specifically target a particular pathogen to destroy it. This specificity makes the immune system more effective. The immune system is also efficient because each antibody does not need to have its own gene.

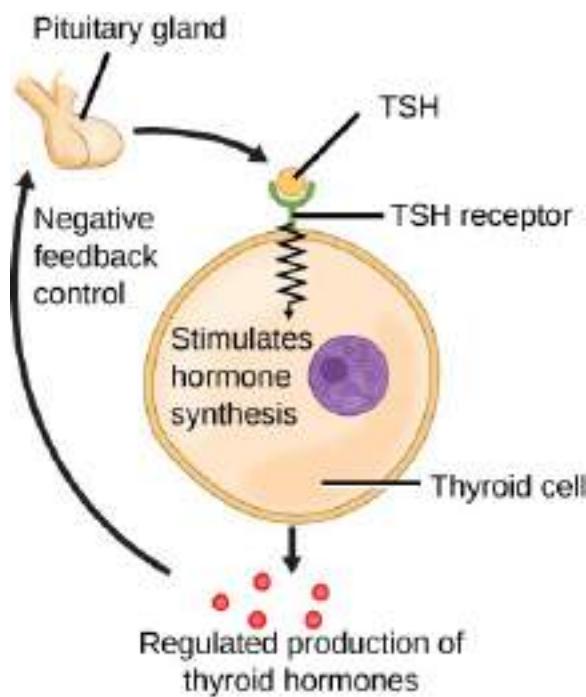

54.

An allergy is caused by the immune system reacting to a foreign protein to produce IgE molecules that recognize the protein. These IgE molecules become associated with mast cells that respond to future exposures to the protein by releasing histamines into the body. The diagram shows this release and also shows how a drug called an antihistamine can help an allergy sufferer reduce their allergy symptoms. Which of the following statements explains how an antihistamine helps restore homeostasis during an allergic reaction?

- Antihistamines prevent mast cells from becoming associated with IgE molecules that recognize the foreign protein allergen.
- Antihistamines prevent mast cells from releasing histamines and causing the unpleasant allergy symptoms.
- Antihistamines prevent histamines that have been released by mast cells from stimulating the itching and swelling of body tissues.
- Antihistamines prevent mast cells from producing histamines, which halts their effect on the body.

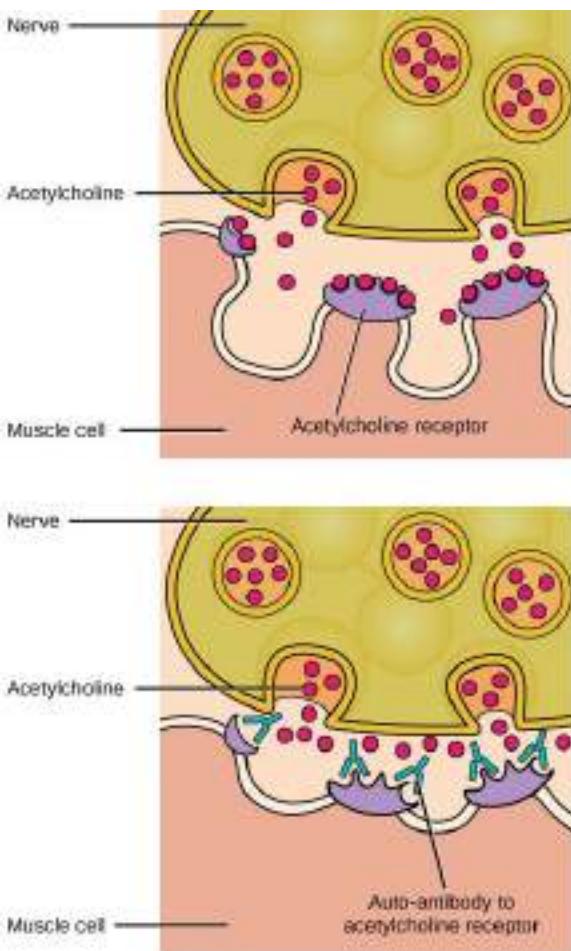

55.

The diagram shows the normal feedback loop that controls the production of thyroid hormones in the human body. Graves' disease is an autoimmune disease in which the body produces autoantibodies to the TSH receptor. When these autoantibodies bind to the receptor, it mimics the action of the TSH hormone. How would the feedback loop and the regulated production of thyroid hormones shown in the diagram be affected in a person with Graves' disease?

- The feedback loop would be disrupted. Autoantibodies would bind to the TSH receptors, allowing them to continue to produce thyroid hormones. As a result, there would be an overproduction of thyroid hormones because the negative feedback system would be unable to function.
- The feedback loop would be not be disrupted. Autoantibodies would bind to the TSH receptors, allowing them to continue to produce thyroid hormones. As a result, there would be an overproduction of thyroid hormones because the negative feedback system would be unable to function.
- The feedback loop would be disrupted. Autoantibodies would not bind to the TSH receptors, allowing them to continue to produce thyroid hormones. As a result, there would be an overproduction of thyroid hormones because the negative feedback system would be unable to function.
- The feedback loop would be disrupted. Autoantibodies would bind to the TSH receptors, allowing them to continue to produce thyroid hormones. As a result, there would be an overproduction of thyroid hormones because the negative feedback system was functional.

56.

Myasthenia gravis is an autoimmune disease that initially presents with muscle weakness and can progress to complete impairment of muscle movement. The diagram compares a healthy individual with an individual suffering from this disease. Which statement best explains what happens to bring about this disease?

- The body produces antibodies against nerve cells, which prevents the nerve cells from releasing acetylcholine during signal transmissions to muscle.
- The body produces antibodies against acetylcholine, which prevents acetylcholine from transmitting signals from nerves to muscle.
- The body produces antibodies against receptors in muscle, which prevents acetylcholine from binding and completing nerve signal transmission.
- The body produces antibodies against acetylcholine, which prevents acetylcholine from breaking down after signal transmission is complete.

## SCIENCE PRACTICE CHALLENGE QUESTIONS

**57. Describe** the difference between the mammalian cell-mediated and humoral responses to a pathogen. Include in your description the roles of antigens and antibodies, T-cells, B-cells, inoculation with vaccines, and the relative response times.

**58. Immune response** must recognize threat by distinguishing wellness from un-wellness. Recognition of pathogen-generated antigens is an adaptive response. Generic pathogen identifiers such as bacterial surface polysaccharides or viral capsid proteins are recognized by cells of the innate immune system. However, cellular debris and dysfunctional whole cells such as tumor cells or cells marked for apoptosis must also be recognized for autophagy (“self-devouring”) by the innate immune system.

A. **Describe** the characteristics of a model of innate immunity that distinguishes wellness from un-wellness without the specificity of antigen receptors.

Autoimmunity is the breakdown in the immune system’s ability to distinguish self from non-self. The list of diseases categorized as autoimmune diseases grows, as does the intensity of research into the causes. One criterion for classification as an autoimmune disease is the presence

of high antibody concentrations in the blood. An autoinflammatory disease is defined by chronic inflammation, unprovoked by an infection, when antibody concentrations are not high. Consider the following:

- Macrophages and phagocytes share information with the adaptive immune system by displaying protein fragments of their targets on their surfaces to communicate with T cells.
- The onset of autoimmune disease often follows an infection.
- After an infection has passed, tissue must be repaired, and macrophages and phagocytes remain active in the affected tissue, often leading to chronic inflammation.
- Type 2 diabetes, traditionally categorized as a metabolic disease, begins as chronic inflammation and is now classified as an autoimmune disease by many scientists.
- Autophagy is induced by stresses such as starvation.

B. **Evaluate** the strength of the **question**, do cell fragments produced by the innate immune response during inflammation communicate self as non-self to T cells

leading to autoimmunity?

In the “fight or flight” response, neural signals are sent to the adrenal gland activating the release of epinephrine. Epinephrine increases metabolic activity, heart rate and alertness. The activation of the endocrine system by the nervous system has been positively selected by survival in response to threat.

C. **Describe** a model for the evolution of the activation of immune system by the nervous system in an environment in which wounds are frequent and potentially lethal. Include the selection process in your description.

In the famous experiment of Pavlov, a reward (unconditioned stimulus) received synchronously with a bell (conditioned stimulus) became associated in the mind of the dog. After a few repetitions, the response of the dog to the bell was to drool. The digestive system had been activated by the nervous system through a conditioned stimulus.

An emerging area of research is psychoneuroimmunology, the study of the relationship between the immune system and the nervous system. Exton and co-workers (*Brain*

*Behavioral Research*, 110, 2000) have shown that a reward (an injection of epinephrine) received synchronously with candy (conditioned stimulus) become associated through repetition. The response of the patient to a shot of epinephrine is the proliferation of natural killer, NK, cells (a cell type of the innate immune system). After conditioning, the patient displayed an increase in NK cells in response to the candy.

The drug cyclosporine is used to suppress immune rejection of organ transplants by inhibiting production of interleukin, a cytokine messenger that increases expression in T cells.

D. **Design an experiment** to test the use of conditioning using the administration of cyclosporine as the unconditioned stimulus and sugar water as the conditioned stimulus by measuring the blood concentration of interleukin. Assume that interleukin is flushed from the blood in a single day. In your design include a vehicle control where conditions are identical to the treatment and a “do-nothing” or naïve control.

# 34 | ANIMAL REPRODUCTION AND DEVELOPMENT

**Figure 34.1** Female seahorses produce eggs for reproduction that are then fertilized by the male. Unlike almost all other animals, the male seahorse then gestates the young until birth. (credit: modification of work by "cliff1066"/Flickr)

## Chapter Outline

- 34.1: Reproduction Methods**
- 34.2: Fertilization**
- 34.3: Human Reproductive Anatomy and Gametogenesis**
- 34.4: Hormonal Control of Human Reproduction**
- 34.5: Fertilization and Early Embryonic Development**
- 34.6: Organogenesis and Vertebrate Formation**
- 34.7: Human Pregnancy and Birth**

## Introduction

Animal reproduction is necessary for the survival of a species. In the animal kingdom, there are innumerable ways that species reproduce. Asexual reproduction produces genetically identical organisms (clones), whereas in sexual reproduction, the genetic material of two individuals combines to produce offspring that are genetically different from their parents. During sexual reproduction the male gamete (sperm) may be placed inside the female's body for internal fertilization, or the sperm and eggs may be released into the environment for external fertilization. Seahorses, like the one shown in **Figure 34.1**,

**34.1**, provide an example of the latter. Following a mating dance, the female lays eggs in the male seahorse's abdominal brood pouch where they are fertilized. The eggs hatch and the offspring develop in the pouch for several weeks.

Some animals are able to reproduce asexually by a process called parthenogenesis. While this process is common in invertebrate animals, it is rare in vertebrates. At first scientists thought that vertebrate parthenogenesis happened only with captive animals, such as birds, snakes, and sharks; however, it was recently discovered that about one in five smalltooth sawfish in Florida is the result of parthenogenesis. This species of fish is endangered, and researchers suspect that this form of reproduction may be an adaptation to help keep the species from going extinct. You can read more about this exciting research [here](http://openstaxcollege.org/l/32ocgiant) (<http://openstaxcollege.org/l/32ocgiant>) .

## 34.1 | Reproduction Methods

In this section, you will explore the following questions:

- What are advantages and disadvantages of asexual and sexual reproduction?
- What are examples of methods of asexual reproduction among animals?
- What are examples of methods of sexual reproduction among animals?

### Connection for AP® Courses

Much of the information about the different reproductive systems of animals is not within the scope for AP®. You likely studied human reproduction in a health course or previous biology course. Reproduction is necessary for the survival of a species, and animals have evolved various reproductive strategies. In a previous chapter we learned that asexual reproduction via mitosis produces genetically identical organisms (clones). We also previously explored how meiosis followed by **sexual reproduction** produces offspring that are genetically different from their parents. Whether or not the material in this chapter is required or illustrative as part of your AP® course, you should find the concepts interesting and relevant to your lives outside the classroom.

Both asexual and sexual reproductive strategies have their advantages and disadvantages. Organisms that reproduce asexually—for example, bacteria and some eukaryotes—may be at a disadvantage in an unstable or unpredictable environment because, barring mutation, the identical offspring may not have sufficient genetic variation to survive in new or different conditions. On the other hand, the rapid rates of **asexual reproduction** may allow a speedy response to changing environmental conditions. Although sexual reproduction allows for greater genetic variation in offspring, organisms that reproduce sexually must maintain males and females in the population, which can limit the ability to colonize new habitats.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 3 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

## Asexual Reproduction

Asexual reproduction occurs in prokaryotic microorganisms (bacteria) and in some eukaryotic single-celled and multi-celled organisms. There are a number of ways that animals reproduce asexually.

### Fission

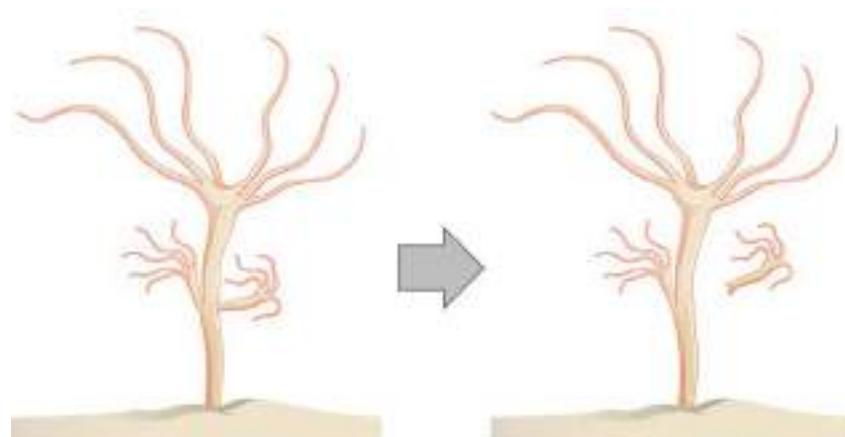

**Fission**, also called binary fission, occurs in prokaryotic microorganisms and in some invertebrate, multi-celled organisms. After a period of growth, an organism splits into two separate organisms. Some unicellular eukaryotic organisms undergo binary fission by mitosis. In other organisms, part of the individual separates and forms a second individual. This process occurs, for example, in many asteroid echinoderms through splitting of the central disk. Some sea anemones and some coral polyps (Figure 34.2) also reproduce through fission.

**Figure 34.2** Coral polyps reproduce asexually by fission. (credit: G. P. Schmahl, NOAA FGBNMS Manager)

### Budding

**Budding** is a form of asexual reproduction that results from the outgrowth of a part of a cell or body region leading to a separation from the original organism into two individuals. Budding occurs commonly in some invertebrate animals such as corals and hydras. In hydras, a bud forms that develops into an adult and breaks away from the main body, as illustrated in Figure 34.3, whereas in coral budding, the bud does not detach and multiplies as part of a new colony.

**Figure 34.3** Hydra reproduce asexually through budding.

Watch a [video](http://openstaxcollege.org/l/budding_hydra) ([http://openstaxcollege.org/l/budding\\_hydra](http://openstaxcollege.org/l/budding_hydra)) of a hydra budding.

Hydras can reproduce through budding. How will the daughter hydra appear?

- a. genetically identical to the mother
- b. not genetically identical to the mother
- c. genetically unique
- d. smaller in size

### Fragmentation

**Fragmentation** is the breaking of the body into two parts with subsequent regeneration. If the animal is capable of fragmentation, and the part is big enough, a separate individual will regrow.

For example, in many sea stars, asexual reproduction is accomplished by fragmentation. **Figure 34.4** illustrates a sea star for which an arm of the individual is broken off and regenerates a new sea star. Fisheries workers have been known to try to kill the sea stars eating their clam or oyster beds by cutting them in half and throwing them back into the ocean. Unfortunately for the workers, the two parts can each regenerate a new half, resulting in twice as many sea stars to prey upon the oysters and clams. Fragmentation also occurs in annelid worms, turbellarians, and poriferans.

**Figure 34.4** Sea stars can reproduce through fragmentation. The large arm, a fragment from another sea star, is developing into a new individual.

Note that in fragmentation, there is generally a noticeable difference in the size of the individuals, whereas in fission, two individuals of approximate size are formed.

### Parthenogenesis

**Parthenogenesis** is a form of asexual reproduction where an egg develops into a complete individual without being fertilized. The resulting offspring can be either haploid or diploid, depending on the process and the species. Parthenogenesis occurs in invertebrates such as water flees, rotifers, aphids, stick insects, some ants, wasps, and bees. Bees and wasps use parthenogenesis to produce haploid males (called drones). If an egg is fertilized, it develops as a diploid female.

Some vertebrate animals—such as certain reptiles, amphibians, and fish—also reproduce through parthenogenesis. Although more common in plants, parthenogenesis has been observed in animal species that were segregated by sex in terrestrial or marine zoos. Two female Komodo dragons, a hammerhead shark, and a blacktop shark have produced parthenogenetic young when the females have been isolated from males.

## Sexual Reproduction

Sexual reproduction is the combination of (usually haploid) reproductive cells from two individuals to form a third (usually diploid) unique offspring. Sexual reproduction produces offspring with novel combinations of genes. This can be an adaptive advantage in unstable or unpredictable environments. As humans, we are used to thinking of animals as having two separate sexes—male and female—determined at conception. However, in the animal kingdom, there are many variations on this theme.

## science practices CONNECTION for AP<sup>®</sup> Courses

### Lab Investigation

*AP<sup>®</sup> Biology Investigative Labs: Inquiry-Based, Investigation 7: Cell Division: Mitosis and Meiosis.* Design and conduct a series of experiments to investigate how eukaryotic cells divide to produce genetically identical cells or to produce gametes with half the normal DNA.

### Think About It

Why is sexual reproduction useful if two separate cells must be combined to form a third?

### Hermaphroditism

**Hermaphroditism** occurs in animals where one individual has both male and female reproductive parts. Invertebrates such as earthworms, slugs, tapeworms and snails, shown in **Figure 34.5**, are often hermaphroditic. Hermaphrodites may self-

fertilize or may mate with another of their species, fertilizing each other and both producing offspring. Self fertilization is common in animals that have limited mobility or are not motile, such as barnacles and clams.

**Figure 34.5** Many snails are hermaphrodites. When two individuals mate, they can produce up to one hundred eggs each. (credit: Assaf Shtilman)

## Sex Determination

Mammalian sex determination is determined genetically by the presence of X and Y chromosomes. Individuals homozygous for X (XX) are female and heterozygous individuals (XY) are male. The presence of a Y chromosome causes the development of male characteristics and its absence results in female characteristics. The XY system is also found in some insects and plants.

Avian sex determination is dependent on the presence of Z and W chromosomes. Homozygous for Z (ZZ) results in a male and heterozygous (ZW) results in a female. The W appears to be essential in determining the sex of the individual, similar to the Y chromosome in mammals. Some fish, crustaceans, insects (such as butterflies and moths), and reptiles use this system.

The sex of some species is not determined by genetics but by some aspect of the environment. Sex determination in some crocodiles and turtles, for example, is often dependent on the temperature during critical periods of egg development. This is referred to as environmental sex determination, or more specifically as temperature-dependent sex determination. In many turtles, cooler temperatures during egg incubation produce males and warm temperatures produce females. In some crocodiles, moderate temperatures produce males and both warm and cool temperatures produce females. In some species, sex is both genetic- and temperature-dependent.

Individuals of some species change their sex during their lives, alternating between male and female. If the individual is female first, it is termed protogyny or “first female,” if it is male first, its termed protandry or “first male.” Oysters, for example, are born male, grow, and become female and lay eggs; some oyster species change sex multiple times.

## everyday CONNECTION for AP<sup>®</sup> Courses

The temperature during incubation determines the sex of loggerhead sea turtles while developing in their eggs. If the temperature is warm enough, all will be females. If the temperature is cooler, all will be males. If the temperature is just right, called the pivotal temperature, then there will be about half females and half males.

**Figure 34.6** (credit: Hillebrand Steve, U.S. Fish and Wildlife Service)

Many species of plants, including the sunflower pictured here, are capable of self-fertilization. If pollination does not occur with the help of pollinating insects, the stigma of the flower will wrap itself around the pollen of the same flower. Although self-fertilization forms seeds by meiosis, all of the resulting plants will be identical. In other words, self-fertilization decreases genetic diversity.

**Figure 34.7** (credit: Wikipedia Commons, *Helianthus annuus*)

The sex of some crocodiles and turtles is dependent on the temperature during critical points in egg development. How

is sex determined in mammalian species?

- a. genetics
- b. nutrition
- c. temperature
- d. genetics and temperature

## 34.2 | Fertilization

In this section, you will explore the following questions:

- What are the differences between internal and external methods of fertilization?
- What are examples of methods animals use for development of offspring during gestation?
- What are examples of anatomical adaptations that evolved in animals to facilitate reproduction?

### Connection for AP<sup>®</sup> Courses

Sexual reproduction starts with the combination of a sperm and an egg in a process called fertilization. The methods of fertilization described in this section are not within the scope for AP<sup>®</sup>. However, from an evolutionary perspective, it is important to note that animals exhibit means of both **external fertilization** and **internal fertilization**, likely determined by their environment. In aquatic environments, water conveys sperm to egg (as in fish and amphibians), but in most terrestrial animals (such as reptiles, birds, and mammals), fertilization occurs internally. The adaptation of the shelled (**amniote**) egg with extraembryonic membranes in reptiles and birds allowed offspring to develop in the conditions associated with land, particularly the lack of water. Placental mammals, including humans, retain the embryo in the female's body until birth.

Information presented and examples highlighted in this section are not within the scope for AP<sup>®</sup> and do not align to the Curriculum Framework.

### External Fertilization

External fertilization usually occurs in aquatic environments where both eggs and sperm are released into the water. After the sperm reaches the egg, fertilization takes place. Most external fertilization happens during the process of spawning where one or several females release their eggs and the male(s) release sperm in the same area, at the same time. The release of the reproductive material may be triggered by water temperature or the length of daylight. Nearly all fish spawn, as do crustaceans (such as crabs and shrimp), mollusks (such as oysters), squid, and echinoderms (such as sea urchins and sea cucumbers). **Figure 34.8** shows salmon spawning in a shallow stream. Frogs, like those shown in **Figure 34.9**, corals, squid, and octopuses also spawn.

**Figure 34.8** Salmon reproduce through spawning. (credit: Dan Bennett)

**Figure 34.9** During sexual reproduction in toads, the male grasps the female from behind and externally fertilizes the eggs as they are deposited. (credit: "OakleyOriginals"/Flickr)

Pairs of fish that are not broadcast spawners may exhibit courtship behavior. This allows the female to select a particular male. The trigger for egg and sperm release (spawning) causes the egg and sperm to be placed in a small area, enhancing the possibility of fertilization.

External fertilization in an aquatic environment protects the eggs from drying out. Broadcast spawning can result in a greater mixture of the genes within a group, leading to higher genetic diversity and a greater chance of species survival in a hostile environment. For sessile aquatic organisms like sponges, broadcast spawning is the only mechanism for fertilization and colonization of new environments. The presence of the fertilized eggs and developing young in the water provides opportunities for predation resulting in a loss of offspring. Therefore, millions of eggs must be produced by individuals, and the offspring produced through this method must mature rapidly. The survival rate of eggs produced through broadcast spawning is low.

## Internal Fertilization

Internal fertilization occurs most often in land-based animals, although some aquatic animals also use this method. There are three ways that offspring are produced following internal fertilization. In **oviparity**, fertilized eggs are laid outside the female's body and develop there, receiving nourishment from the yolk that is a part of the egg. This occurs in most bony fish, many reptiles, some cartilaginous fish, most amphibians, two mammals, and all birds. Reptiles and insects produce leathery eggs, while birds and turtles produce eggs with high concentrations of calcium carbonate in the shell, making them hard. Chicken eggs are an example of this second type.

In **ovoviparity**, fertilized eggs are retained in the female, but the embryo obtains its nourishment from the egg's yolk and the young are fully developed when they are hatched. This occurs in some bony fish (like the guppy *Lebistes reticulatus*), some sharks, some lizards, some snakes (such as the garter snake *Thamnophis sirtalis*), some vipers, and some invertebrate animals (like the Madagascar hissing cockroach *Gromphadorhina portentosa*).

In **viviparity** the young develop within the female, receiving nourishment from the mother's blood through a placenta. The offspring develops in the female and is born alive. This occurs in most mammals, some cartilaginous fish, and a few reptiles.

Internal fertilization has the advantage of protecting the fertilized egg from dehydration on land. The embryo is isolated within the female, which limits predation on the young. Internal fertilization enhances the fertilization of eggs by a specific male. Fewer offspring are produced through this method, but their survival rate is higher than that for external fertilization.

## The Evolution of Reproduction

Once multicellular organisms evolved and developed specialized cells, some also developed tissues and organs with specialized functions. An early development in reproduction occurred in the Annelids. These organisms produce sperm and eggs from undifferentiated cells in their coelom and store them in that cavity. When the coelom becomes filled, the cells are

released through an excretory opening or by the body splitting open. Reproductive organs evolved with the development of gonads that produce sperm and eggs. These cells went through meiosis, an adaption of mitosis, which reduced the number of chromosomes in each reproductive cell by half, while increasing the number of cells through cell division.

Complete reproductive systems were developed in insects, with separate sexes. Sperm are made in testes and then travel through coiled tubes to the epididymis for storage. Eggs mature in the ovary. When they are released from the ovary, they travel to the uterine tubes for fertilization. Some insects have a specialized sac, called a **spermatheca**, which stores sperm for later use, sometimes up to a year. Fertilization can be timed with environmental or food conditions that are optimal for offspring survival.

Vertebrates have similar structures, with a few differences. Non-mammals, such as birds and reptiles, have a common body opening, called a **cloaca**, for the digestive, excretory and reproductive systems. Coupling between birds usually involves positioning the cloaca openings opposite each other for transfer of sperm. Mammals have separate openings for the systems in the female and a uterus for support of developing offspring. The uterus has two chambers in species that produce large numbers of offspring at a time, while species that produce one offspring, such as primates, have a single uterus.

Sperm transfer from the male to the female during reproduction ranges from releasing the sperm into the watery environment for external fertilization, to the joining of cloaca in birds, to the development of a penis for direct delivery into the female's vagina in mammals.

## science practices CONNECTION for AP<sup>®</sup> Courses

### Think About It

The measure of an individual's reproductive success is based on its ability to produce offspring. What adaptations would a male have to have to be reproductively successful if his species utilizes external fertilization? Internal fertilization?

## 34.3 | Human Reproductive Anatomy and Gametogenesis

In this section, you will explore the following questions:

- What are the features of the human male and female reproductive anatomies?
- What are the events associated with the human sexual response?
- What are the differences and similarities between spermatogenesis and oogenesis?

### Connection for AP<sup>®</sup> Courses

Much of the information in this section is not within the scope for AP<sup>®</sup>. You do not need to match a list of the different anatomical features of the male and female reproductive systems with their functions, but you likely will find the material informative and relevant. The reproductive structures that evolved in land animals, including humans, allow males and females to mate, fertilize internally, and support the growth and development of offspring. The section provides an opportunity to review the process of meiosis that we first explored in a previous chapter.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 3 of the AP<sup>®</sup> Biology Curriculum Framework. The AP<sup>®</sup> Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

#### Big Idea 3

## Human Reproductive Anatomy

The reproductive tissues of male and female humans develop similarly *in utero* until a low level of the hormone testosterone is released from male gonads. Testosterone causes the undeveloped tissues to differentiate into male sexual organs. When testosterone is absent, the tissues develop into female sexual tissues. Primitive gonads become testes or ovaries. Tissues that produce a penis in males produce a clitoris in females. The tissue that will become the scrotum in a male becomes the labia in a female; that is, they are homologous structures.

### Male Reproductive Anatomy

In the male reproductive system, the **scrotum** houses the testicles or testes (singular: testis), including providing passage for blood vessels, nerves, and muscles related to testicular function. The **testes** are a pair of male reproductive organs that produce sperm and some reproductive hormones. Each testis is approximately 2.5 by 3.8 cm (1.5 by 1 in) in size and divided into wedge-shaped lobules by connective tissue called septa. Coiled in each wedge are seminiferous tubules that produce sperm.

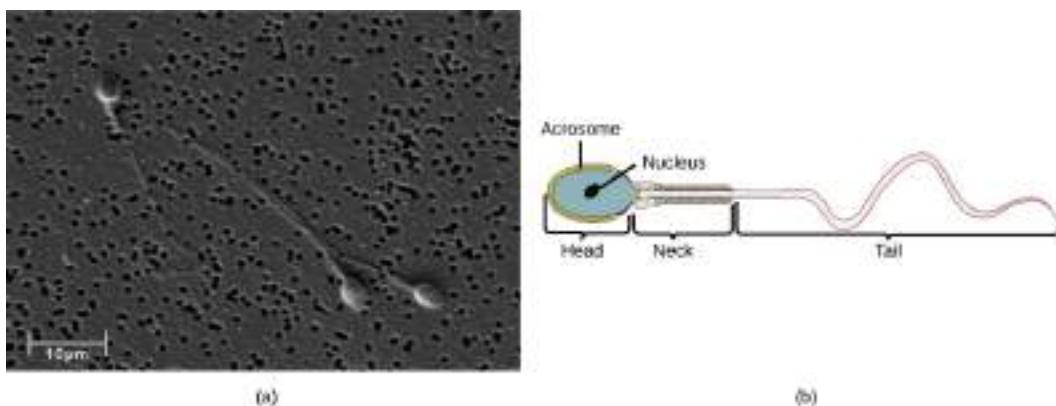

Sperm are immobile at body temperature; therefore, the scrotum and penis are external to the body, as illustrated in **Figure 34.10** so that a proper temperature is maintained for motility. In land mammals, the pair of testes must be suspended outside the body at about 2° C lower than body temperature to produce viable sperm. Infertility can occur in land mammals when the testes do not descend through the abdominal cavity during fetal development.

Sperm mature in **seminiferous tubules** that are coiled inside the testes, as illustrated in **Figure 34.10**. The walls of the seminiferous tubules are made up of the developing sperm cells, with the least developed sperm at the periphery of the tubule and the fully developed sperm in the lumen. The sperm cells are mixed with “nursemaid” cells called Sertoli cells which protect the germ cells and promote their development. Other cells mixed in the wall of the tubules are the interstitial cells of Leydig. These cells produce high levels of testosterone once the male reaches adolescence.

When the sperm have developed flagella and are nearly mature, they leave the testicles and enter the epididymis, shown in **Figure 34.10**. This structure resembles a comma and lies along the top and posterior portion of the testes; it is the site of sperm maturation. The sperm leave the epididymis and enter the vas deferens (or ductus deferens), which carries the sperm, behind the bladder, and forms the ejaculatory duct with the duct from the seminal vesicles. During a vasectomy, a section of the vas deferens is removed, preventing sperm from being passed out of the body during ejaculation and preventing fertilization.

**Semen** is a mixture of sperm and spermatocytic duct secretions (about 10 percent of the total) and fluids from accessory glands that contribute most of the semen’s volume. Sperm are haploid cells, consisting of a flagellum as a tail, a neck that contains the cell’s energy-producing mitochondria, and a head that contains the genetic material. **Figure 34.11** shows a micrograph of human sperm as well as a diagram of the parts of the sperm. An acrosome is found at the top of the head of the sperm. This structure contains lysosomal enzymes that can digest the protective coverings that surround the egg to help the sperm penetrate and fertilize the egg. An ejaculate will contain from two to five milliliters of fluid with from 50–120 million sperm per milliliter.

**Figure 34.11** Human sperm, visualized using scanning electron microscopy, have a flagellum, neck, and head. (credit b: modification of work by Mariana Ruiz Villareal; scale-bar data from Matt Russell)

The bulk of the semen comes from the accessory glands associated with the male reproductive system. These are the seminal vesicles, the prostate gland, and the bulbourethral gland, all of which are illustrated in **Figure 34.10**. The **seminal vesicles** are a pair of glands that lie along the posterior border of the urinary bladder. The glands make a solution that is thick, yellowish, and alkaline. As sperm are only motile in an alkaline environment, a basic pH is important to reverse the acidity of the vaginal environment. The solution also contains mucus, fructose (a sperm mitochondrial nutrient), a coagulating enzyme, ascorbic acid, and local-acting hormones called prostaglandins. The seminal vesicle glands account for 60 percent of the bulk of semen.

The **penis**, illustrated in **Figure 34.10**, is an organ that drains urine from the renal bladder and functions as a copulatory organ during intercourse. The penis contains three tubes of erectile tissue running through the length of the organ. These consist of a pair of tubes on the dorsal side, called the corpus cavernosum, and a single tube of tissue on the ventral side, called the corpus spongiosum. This tissue will become engorged with blood, becoming erect and hard, in preparation for intercourse. The organ is inserted into the vagina culminating with an ejaculation. During intercourse, the smooth muscle sphincters at the opening to the renal bladder close and prevent urine from entering the penis. An orgasm is a two-stage process: first, glands and accessory organs connected to the testes contract, then semen (containing sperm) is expelled through the urethra during ejaculation. After intercourse, the blood drains from the erectile tissue and the penis becomes flaccid.

The walnut-shaped **prostate gland** surrounds the urethra, the connection to the urinary bladder. It has a series of short ducts that directly connect to the urethra. The gland is a mixture of smooth muscle and glandular tissue. The muscle provides much of the force needed for ejaculation to occur. The glandular tissue makes a thin, milky fluid that contains citrate (a nutrient), enzymes, and prostate specific antigen (PSA). PSA is a proteolytic enzyme that helps to liquefy the ejaculate several minutes after release from the male. Prostate gland secretions account for about 30 percent of the bulk of semen.

The **bulbourethral gland**, or Cowper's gland, releases its secretion prior to the release of the bulk of the semen. It neutralizes any acid residue in the urethra left over from urine. This usually accounts for a couple of drops of fluid in the total ejaculate and may contain a few sperm. Withdrawal of the penis from the vagina before ejaculation to prevent pregnancy may not work if sperm are present in the bulbourethral gland secretions. The location and functions of the male reproductive organs are summarized in **Table 34.1**.

### Male Reproductive Anatomy

| Organ            | Location | Function                        |
|------------------|----------|---------------------------------|
| Scrotum          | External | Carry and support testes        |
| Penis            | External | Deliver urine, copulating organ |
| Testes           | Internal | Produce sperm and male hormones |
| Seminal Vesicles | Internal | Contribute to semen production  |
| Prostate Gland   | Internal | Contribute to semen production  |

**Table 34.1**

| Organ                | Location | Function                     |
|----------------------|----------|------------------------------|
| Bulbourethral Glands | Internal | Clean urethra at ejaculation |

**Table 34.1**

### Female Reproductive Anatomy

A number of reproductive structures are exterior to the female's body. These include the breasts and the vulva, which consists of the mons pubis, clitoris, labia majora, labia minora, and the vestibular glands, all illustrated in [Figure 34.12](#). The location and functions of the female reproductive organs are summarized in [Table 34.2](#). The vulva is an area associated with the vestibule which includes the structures found in the inguinal (groin) area of women. The mons pubis is a round, fatty area that overlies the pubic symphysis. The **clitoris** is a structure with erectile tissue that contains a large number of sensory nerves and serves as a source of stimulation during intercourse. The **labia majora** are a pair of elongated folds of tissue that run posterior from the mons pubis and enclose the other components of the vulva. The labia majora derive from the same tissue that produces the scrotum in a male. The **labia minora** are thin folds of tissue centrally located within the labia majora. These labia protect the openings to the vagina and urethra. The mons pubis and the anterior portion of the labia majora become covered with hair during adolescence; the labia minora is hairless. The greater vestibular glands are found at the sides of the vaginal opening and provide lubrication during intercourse.

## Female Reproductive Anatomy

| Organ                     | Location | Function                        |
|---------------------------|----------|---------------------------------|
| Clitoris                  | External | Sensory organ                   |
| Mons pubis                | External | Fatty area overlying pubic bone |
| Labia majora              | External | Covers labia minora             |
| Labia minora              | External | Covers vestibule                |
| Greater vestibular glands | External | Secrete mucus; lubricate vagina |
| Breast                    | External | Produce and deliver milk        |
| Ovaries                   | Internal | Carry and develop eggs          |

**Table 34.2**

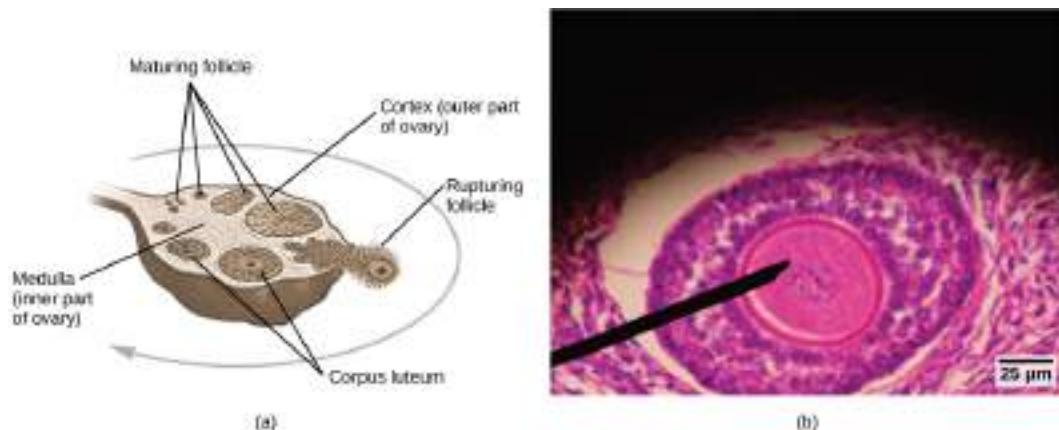

## Female Reproductive Anatomy

| Organ                      | Location | Function                                                         |
|----------------------------|----------|------------------------------------------------------------------|
| Oviducts (Fallopian tubes) | Internal | Transport egg to uterus                                          |
| Uterus                     | Internal | Support developing embryo                                        |
| Vagina                     | Internal | Common tube for intercourse, birth canal, passing menstrual flow |

**Table 34.2**

The breasts consist of mammary glands and fat. The size of the breast is determined by the amount of fat deposited behind the gland. Each gland consists of 15 to 25 lobes that have ducts that empty at the nipple and that supply the nursing child with nutrient- and antibody-rich milk to aid development and protect the child.

Internal female reproductive structures include ovaries, oviducts, the **uterus**, and the vagina, shown in **Figure 34.12**. The pair of ovaries is held in place in the abdominal cavity by a system of ligaments. Ovaries consist of a medulla and cortex: the medulla contains nerves and blood vessels to supply the cortex with nutrients and remove waste. The outer layers of cells of the cortex are the functional parts of the ovaries. The cortex is made up of follicular cells that surround eggs that develop during fetal development *in utero*. During the menstrual period, a batch of follicular cells develops and prepares the eggs for release. At ovulation, one follicle ruptures and one egg is released, as illustrated in **Figure 34.13a**.

**Figure 34.13** Oocytes develop in (a) follicles, located in the ovary. At the beginning of the menstrual cycle, the follicle matures. At ovulation, the follicle ruptures, releasing the egg. The follicle becomes a corpus luteum, which eventually degenerates. The (b) follicle in this light micrograph has an oocyte at its center. (credit a: modification of work by NIH; scale-bar data from Matt Russell)

The **oviducts**, or fallopian tubes, extend from the uterus in the lower abdominal cavity to the ovaries, but they are not in contact with the ovaries. The lateral ends of the oviducts flare out into a trumpet-like structure and have a fringe of finger-like projections called fimbriae, illustrated in **Figure 34.12b**. When an egg is released at ovulation, the fimbriae help the non-motile egg enter into the tube and passage to the uterus. The walls of the oviducts are ciliated and are made up mostly of smooth muscle. The cilia beat toward the middle, and the smooth muscle contracts in the same direction, moving the egg toward the uterus. Fertilization usually takes place within the oviducts and the developing embryo is moved toward the uterus for development. It usually takes the egg or embryo a week to travel through the oviduct. Sterilization in women is called a tubal ligation; it is analogous to a vasectomy in males in that the oviducts are severed and sealed.

The uterus is a structure about the size of a woman's fist. This is lined with an endometrium rich in blood vessels and mucus glands. The uterus supports the developing embryo and fetus during gestation. The thickest portion of the wall of the uterus is made of smooth muscle. Contractions of the smooth muscle in the uterus aid in passing the baby through the vagina during labor. A portion of the lining of the uterus sloughs off during each menstrual period, and then builds up again in preparation for an implantation. Part of the uterus, called the cervix, protrudes into the top of the vagina. The cervix functions as the birth canal.

The **vagina** is a muscular tube that serves several purposes. It allows menstrual flow to leave the body. It is the receptacle for the penis during intercourse and the vessel for the delivery of offspring. It is lined by stratified squamous epithelial cells to protect the underlying tissue.

### Sexual Response during Intercourse

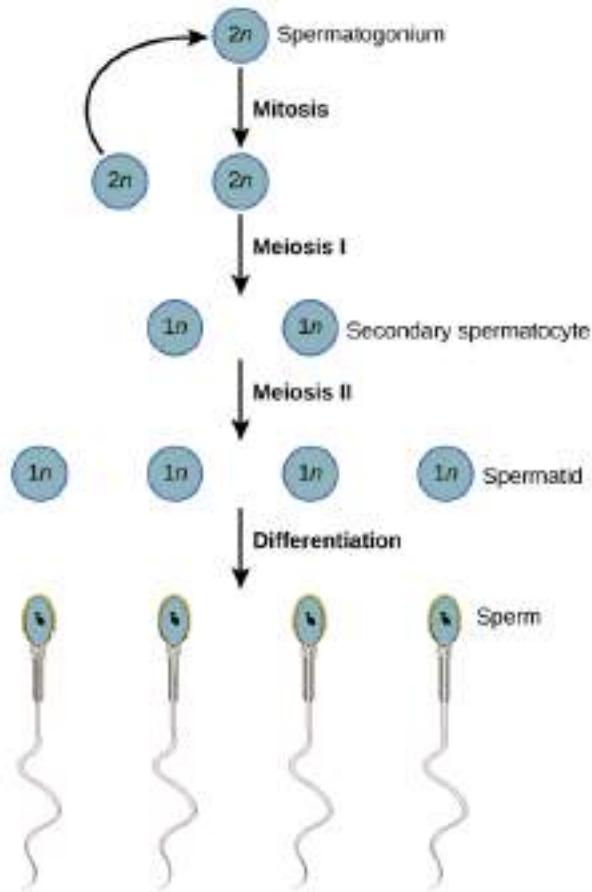

The sexual response in humans is both psychological and physiological. Both sexes experience sexual arousal through psychological and physical stimulation. There are four phases of the sexual response. During phase one, called excitement, vasodilation leads to vasocongestion in erectile tissues in both men and women. The nipples, clitoris, labia, and penis engorge with blood and become enlarged. Vaginal secretions are released to lubricate the vagina to facilitate intercourse. During the second phase, called the plateau, stimulation continues, the outer third of the vaginal wall enlarges with blood, and breathing and heart rate increase.

During phase three, or orgasm, rhythmic, involuntary contractions of muscles occur in both sexes. In the male, the reproductive accessory glands and tubules constrict placing semen in the urethra, then the urethra contracts expelling the semen through the penis. In women, the uterus and vaginal muscles contract in waves that may last slightly less than a second each. During phase four, or resolution, the processes described in the first three phases reverse themselves and return to their normal state. Men experience a refractory period in which they cannot maintain an erection or ejaculate for a period of time ranging from minutes to hours.

## Gametogenesis (Spermatogenesis and Oogenesis)

Gametogenesis, the production of sperm and eggs, takes place through the process of meiosis. During meiosis, two cell divisions separate the paired chromosomes in the nucleus and then separate the chromatids that were made during an earlier stage of the cell's life cycle. Meiosis produces haploid cells with half of each pair of chromosomes normally found in diploid cells. The production of sperm is called **spermatogenesis** and the production of eggs is called **oogenesis**.

### Spermatogenesis

**Figure 34.14** During spermatogenesis, four sperm result from each primary spermatocyte.

Spermatogenesis, illustrated in **Figure 34.14**, occurs in the wall of the seminiferous tubules (**Figure 34.10**), with stem cells at the periphery of the tube and the spermatozoa at the lumen of the tube. Immediately under the capsule of the tubule are diploid, undifferentiated cells. These stem cells, called spermatogonia (singular: spermatagonium), go through mitosis with one offspring going on to differentiate into a sperm cell and the other giving rise to the next generation of sperm.

Meiosis starts with a cell called a primary spermatocyte. At the end of the first meiotic division, a haploid cell is produced called a secondary spermatocyte. This cell is haploid and must go through another meiotic cell division. The cell produced at the end of meiosis is called a spermatid and when it reaches the lumen of the tubule and grows a flagellum, it is called a sperm cell. Four sperm result from each primary spermatocyte that goes through meiosis.

Stem cells are deposited during gestation and are present at birth through the beginning of adolescence, but in an inactive state. During adolescence, gonadotropic hormones from the anterior pituitary cause the activation of these cells and the production of viable sperm. This continues into old age.

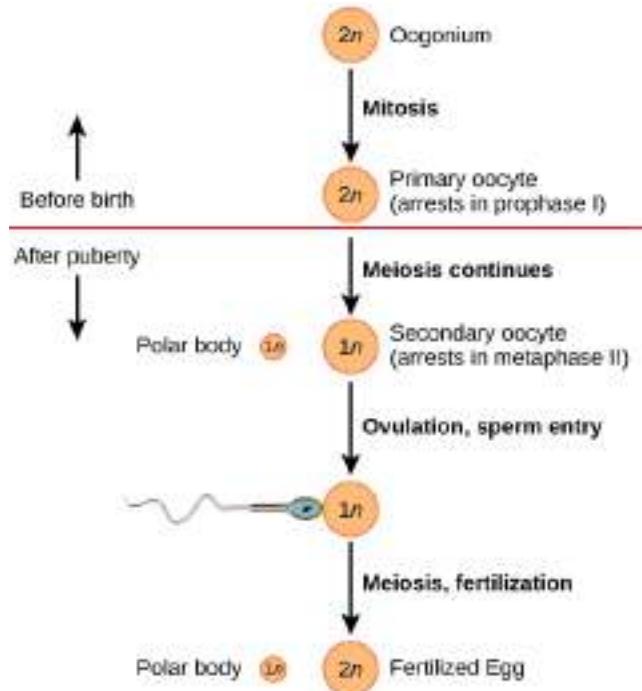

Visit **this site** (<http://openstaxcollege.org/l/spermatogenesis>) to see the process of spermatogenesis.

During spermatogenesis, which cells undergo meiosis to ultimately produce haploid gametes?

- spermatogonia
- primary spermatocytes
- secondary spermatocytes
- spermatids

### Oogenesis

Oogenesis, illustrated in **Figure 34.15**, occurs in the outermost layers of the ovaries. As with sperm production, oogenesis starts with a germ cell, called an oogonium (plural: oogonia), but this cell undergoes mitosis to increase in number, eventually resulting in up to about one to two million cells in the embryo.

**Figure 34.15** The process of oogenesis occurs in the ovary's outermost layer.

The cell starting meiosis is called a primary oocyte, as shown in [Figure 34.15](#). This cell will start the first meiotic division and be arrested in its progress in the first prophase stage. At the time of birth, all future eggs are in the prophase stage. At adolescence, anterior pituitary hormones cause the development of a number of follicles in an ovary. This results in the primary oocyte finishing the first meiotic division. The cell divides unequally, with most of the cellular material and organelles going to one cell, called a secondary oocyte, and only one set of chromosomes and a small amount of cytoplasm going to the other cell. This second cell is called a polar body and usually dies. A secondary meiotic arrest occurs, this time at the metaphase II stage. At ovulation, this secondary oocyte will be released and travel toward the uterus through the oviduct. If the secondary oocyte is fertilized, the cell continues through the meiosis II, producing a second polar body and a fertilized egg containing all 46 chromosomes of a human being, half of them coming from the sperm.

Egg production begins before birth, is arrested during meiosis until puberty, and then individual cells continue through at each menstrual cycle. One egg is produced from each meiotic process, with the extra chromosomes and chromatids going into polar bodies that degenerate and are reabsorbed by the body.

### Think About It

Compare spermatogenesis and oogenesis as to the timing of the processes and the number and type of cells finally produced.

## 34.4 | Hormonal Control of Human Reproduction

In this section, you will explore the following questions:

- What are the roles of male and female reproductive hormones?
- What is the link between the ovarian and menstrual cycles?
- What events are associated with menopause?

### Connection for AP<sup>®</sup> Courses

The information in this section is an application of concepts we learned when exploring the endocrine system in a previous chapter. The human male and female reproductive cycles are regulated by the interaction of hormones from the hypothalamus and anterior pituitary with hormones from reproductive tissues and organs. Detailed knowledge about sperm production and the ovarian and menstrual cycles is not within the scope for AP<sup>®</sup>, and you likely studied this information in a health class. Since the material in this section is practical and relevant, a brief review is helpful.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 and Big Idea 3 of the AP<sup>®</sup> Biology Curriculum Framework. The AP<sup>®</sup> Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Learning Objective</b>         | 3.35 The student is able to create representation(s) that depict how cell-to-cell communication occurs by direct contact or from a distance through chemical signaling. |

## Male Hormones

At the onset of puberty, the hypothalamus causes the release of **follicle stimulating hormone (FSH)** and **luteinizing hormone (LH)** into the male system for the first time. FSH enters the testes and stimulates the **Sertoli cells** to begin facilitating spermatogenesis using negative feedback, as illustrated in **Figure 34.16**. LH also enters the testes and stimulates the **interstitial cells of Leydig** to make and release testosterone into the testes and the blood.

**Testosterone**, the hormone responsible for the secondary sexual characteristics that develop in the male during adolescence, stimulates spermatogenesis. These secondary sex characteristics include a deepening of the voice, the growth of facial, axillary, and pubic hair, and the beginnings of the sex drive.

**Figure 34.16** Hormones control sperm production in a negative feedback system.

A negative feedback system occurs in the male with rising levels of testosterone acting on the hypothalamus and anterior pituitary to inhibit the release of **gonadotropin-releasing hormone (GnRH)**, FSH, and LH. The Sertoli cells produce the hormone **inhibin**, which is released into the blood when the sperm count is too high. This inhibits the release of GnRH and FSH, which will cause spermatogenesis to slow down. If the sperm count reaches 20 million/ml, the Sertoli cells cease the release of inhibin, and the sperm count increases.

## Female Hormones

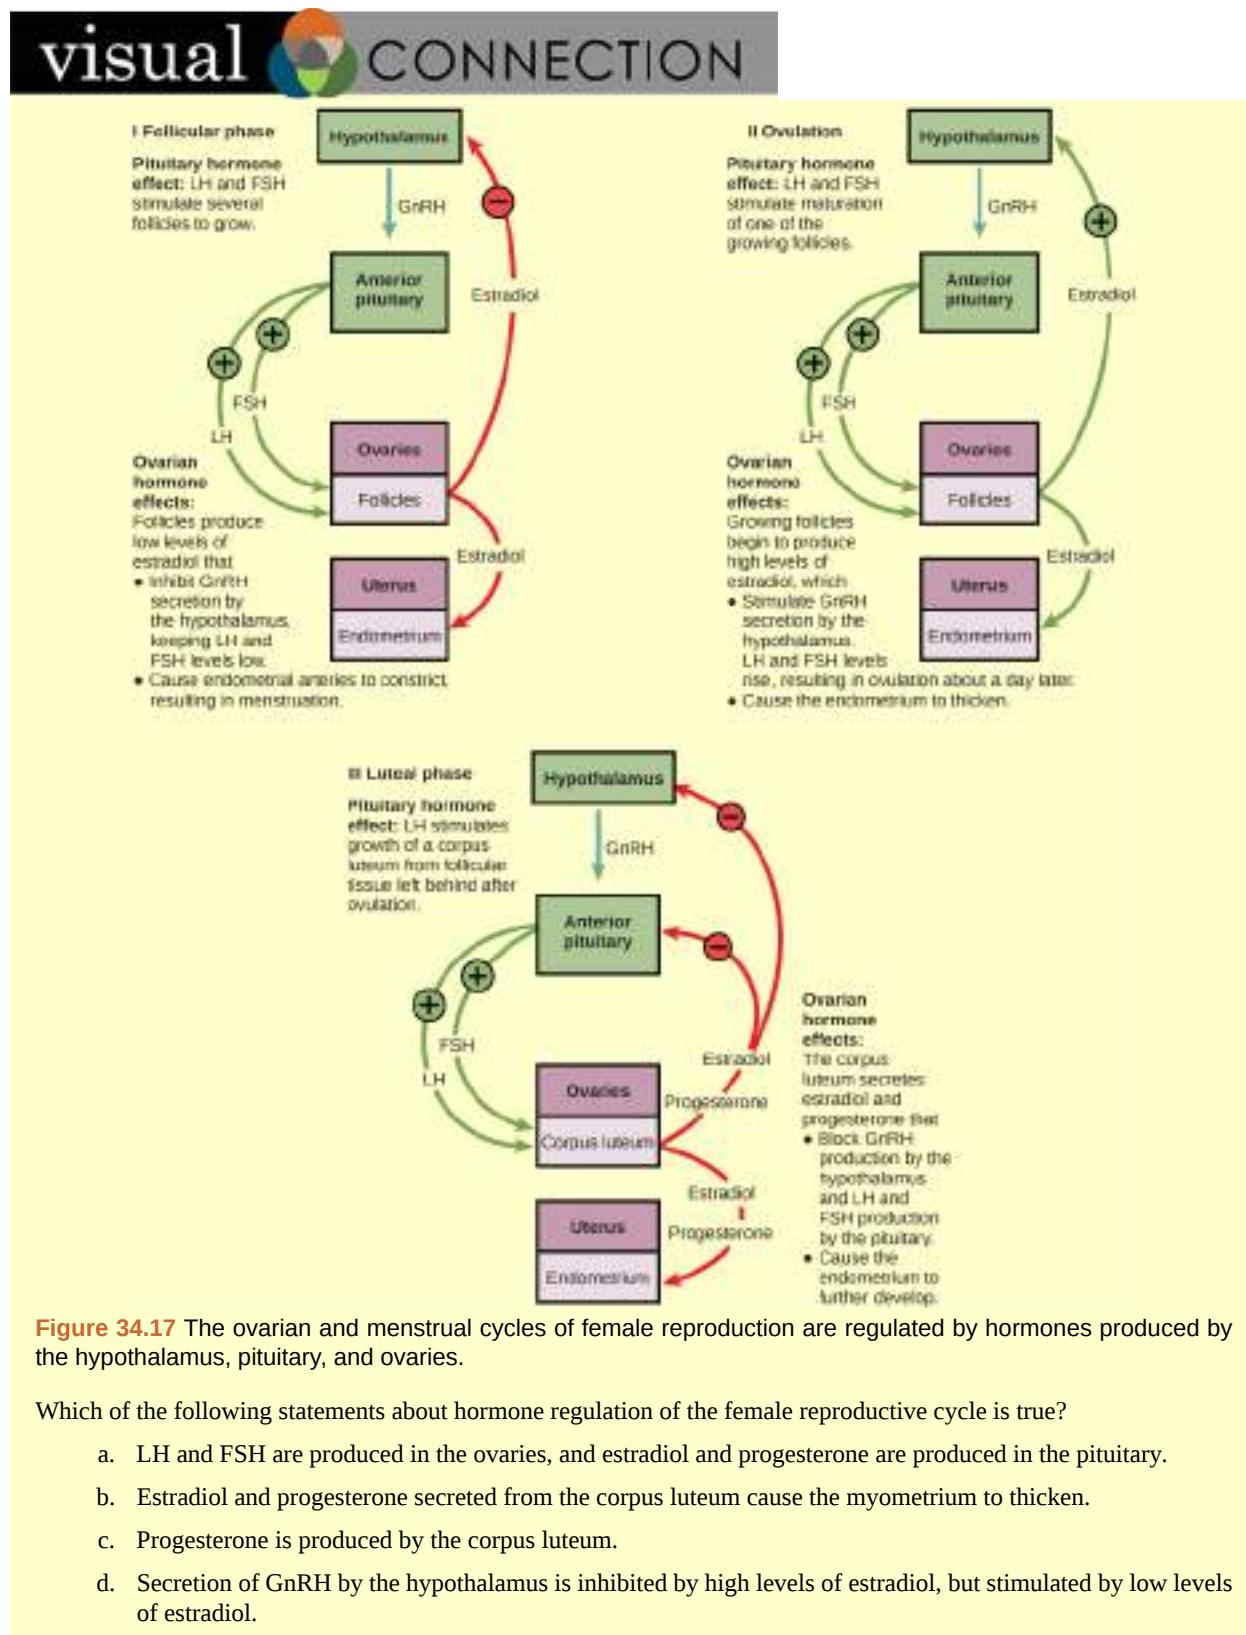

The control of reproduction in females is more complex. As with the male, the anterior pituitary hormones cause the release of the hormones FSH and LH. In addition, estrogens and progesterone are released from the developing follicles. **Estrogen** is the reproductive hormone in females that assists in endometrial regrowth, ovulation, and calcium absorption; it is also responsible for the secondary sexual characteristics of females. These include breast development, flaring of the hips, and a shorter period necessary for bone maturation. **Progesterone** assists in endometrial re-growth and inhibition of FSH and LH release.

In females, FSH stimulates development of egg cells, called ova, which develop in structures called follicles. Follicle cells produce the hormone inhibin, which inhibits FSH production. LH also plays a role in the development of ova, induction of ovulation, and stimulation of estradiol and progesterone production by the ovaries. Estradiol and progesterone are steroid hormones that prepare the body for pregnancy. Estradiol produces secondary sex characteristics in females, while both estradiol and progesterone regulate the menstrual cycle.

### The Ovarian Cycle and the Menstrual Cycle

The **ovarian cycle** governs the preparation of endocrine tissues and release of eggs, while the **menstrual cycle** governs the preparation and maintenance of the uterine lining. These cycles occur concurrently and are coordinated over a 22–32 day cycle, with an average length of 28 days.

The first half of the ovarian cycle is the follicular phase shown in **Figure 34.17**. Slowly rising levels of FSH and LH cause the growth of follicles on the surface of the ovary. This process prepares the egg for ovulation. As the follicles grow, they begin releasing estrogens and a low level of progesterone. Progesterone maintains the endometrium to help ensure pregnancy. The trip through the fallopian tube takes about seven days. At this stage of development, called the morula, there are 30–60 cells. If pregnancy implantation does not occur, the lining is sloughed off. After about five days, estrogen levels rise and the menstrual cycle enters the proliferative phase. The endometrium begins to regrow, replacing the blood vessels and glands that deteriorated during the end of the last cycle.

**Figure 34.17** The ovarian and menstrual cycles of female reproduction are regulated by hormones produced by the hypothalamus, pituitary, and ovaries.

Which of the following statements about hormone regulation of the female reproductive cycle is true?

- LH and FSH are produced in the ovaries, and estradiol and progesterone are produced in the pituitary.
- Estradiol and progesterone secreted from the corpus luteum cause the myometrium to thicken.
- Progesterone is produced by the corpus luteum.
- Secretion of GnRH by the hypothalamus is inhibited by high levels of estradiol, but stimulated by low levels of estradiol.

Just prior to the middle of the cycle (approximately day 14), the high level of estrogen causes FSH and especially LH to rise rapidly, then fall. The spike in LH causes **ovulation**: the most mature follicle, like that shown in **Figure 34.18**, ruptures and

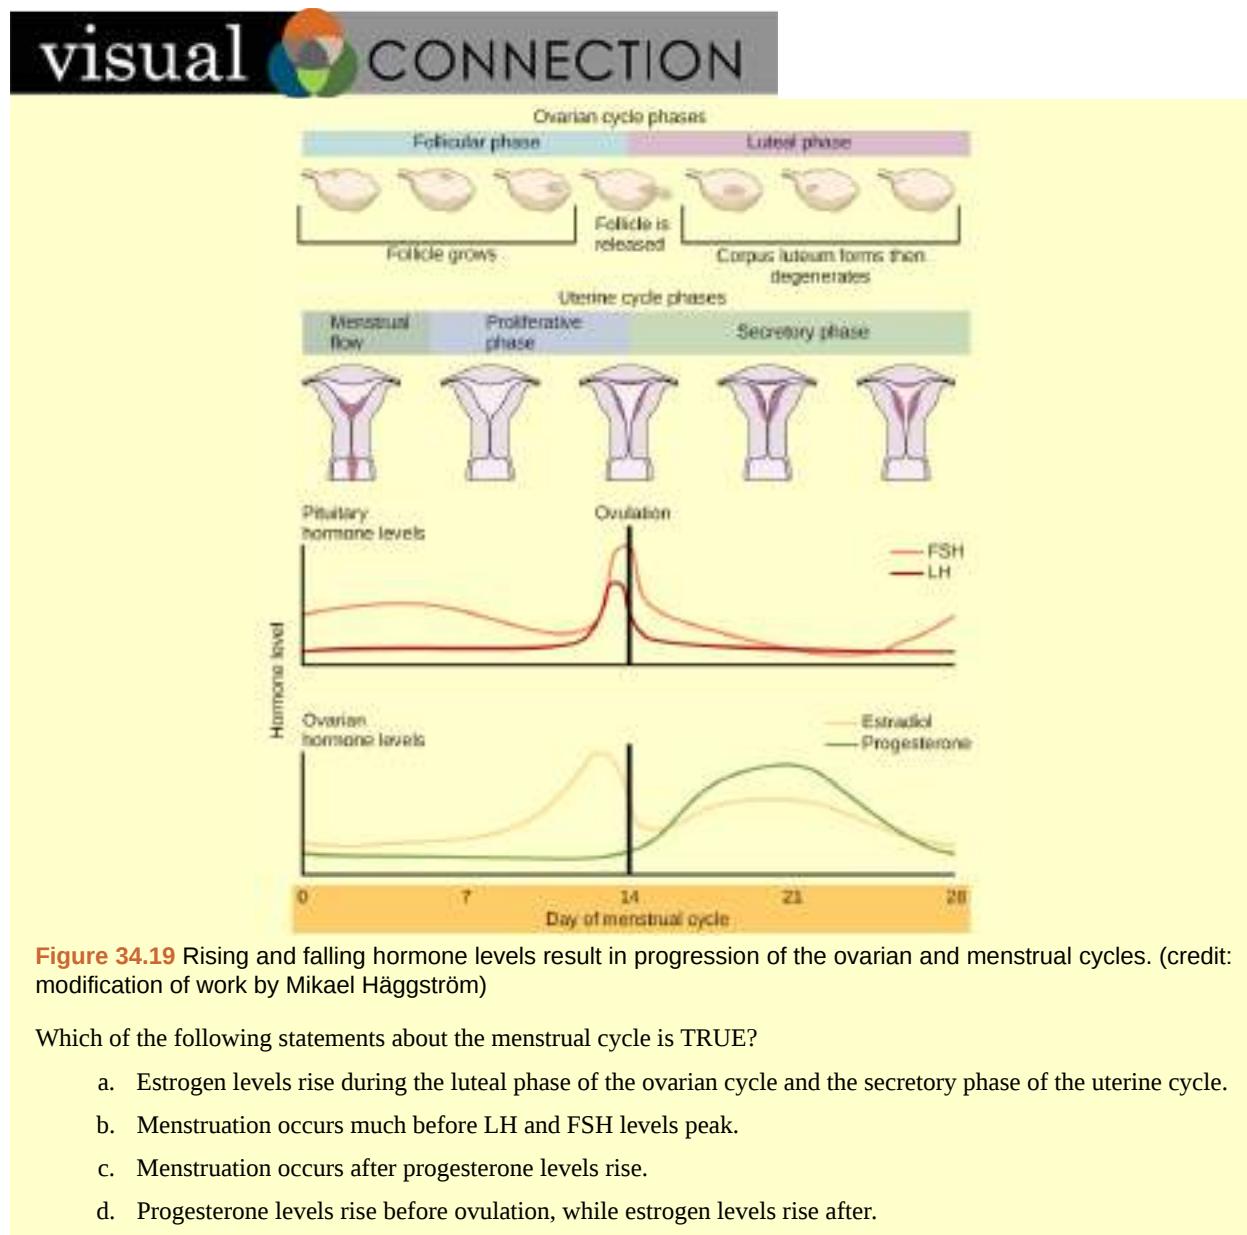

releases its egg. The follicles that did not rupture degenerate and their eggs are lost. The level of estrogen decreases when the extra follicles degenerate.

**Figure 34.18** This mature egg follicle may rupture and release an egg. (credit: scale-bar data from Matt Russell)

Following ovulation, the ovarian cycle enters its luteal phase, illustrated in [Figure 34.17](#) and the menstrual cycle enters its secretory phase, both of which run from about day 15 to 28. The luteal and secretory phases refer to changes in the ruptured follicle. The cells in the follicle undergo physical changes and produce a structure called a corpus luteum. The corpus luteum produces estrogen and progesterone. The progesterone facilitates the regrowth of the uterine lining and inhibits the release of further FSH and LH. The uterus is being prepared to accept a fertilized egg, should it occur during this cycle. The inhibition of FSH and LH prevents any further eggs and follicles from developing, while the progesterone is elevated. The level of estrogen produced by the corpus luteum increases to a steady level for the next few days.

If no fertilized egg is implanted into the uterus, the corpus luteum degenerates and the levels of estrogen and progesterone decrease. The endometrium begins to degenerate as the progesterone levels drop, initiating the next menstrual cycle. The decrease in progesterone also allows the hypothalamus to send GnRH to the anterior pituitary, releasing FSH and LH and starting the cycles again. [Figure 34.19](#) visually compares the ovarian and uterine cycles as well as the commensurate hormone levels.

**Figure 34.19** Rising and falling hormone levels result in progression of the ovarian and menstrual cycles. (credit: modification of work by Mikael Häggström)

Which of the following statements about the menstrual cycle is TRUE?

- Estrogen levels rise during the luteal phase of the ovarian cycle and the secretory phase of the uterine cycle.
- Menstruation occurs much before LH and FSH levels peak.
- Menstruation occurs after progesterone levels rise.
- Progesterone levels rise before ovulation, while estrogen levels rise after.

## science practices CONNECTION for AP® Courses

### Think About It

What are the major events in the ovarian cycle leading up to ovulation, and how are these events regulated by negative feedback mechanisms?

### Menopause

As women approach their mid-40s to mid-50s, their ovaries begin to lose their sensitivity to FSH and LH. Menstrual periods become less frequent and finally cease; this is **menopause**. There are still eggs and potential follicles on the ovaries, but without the stimulation of FSH and LH, they will not produce a viable egg to be released. The outcome of this is the inability to have children.

The side effects of menopause include hot flashes, heavy sweating (especially at night), headaches, some hair loss, muscle pain, vaginal dryness, insomnia, depression, weight gain, and mood swings. Estrogen is involved in calcium metabolism and, without it, blood levels of calcium decrease. To replenish the blood, calcium is lost from bone which may decrease the bone density and lead to osteoporosis. Supplementation of estrogen in the form of hormone replacement therapy (HRT) can prevent bone loss, but the therapy can have negative side effects. While HRT is thought to give some protection from colon cancer, osteoporosis, heart disease, macular degeneration, and possibly depression, its negative side effects include increased risk of: stroke or heart attack, blood clots, breast cancer, ovarian cancer, endometrial cancer, gall bladder disease, and possibly dementia.

## CAREER CONNECTION

### Reproductive Endocrinologist

A reproductive endocrinologist is a physician who treats a variety of hormonal disorders related to reproduction and infertility in both men and women. The disorders include menstrual problems, infertility, pregnancy loss, sexual dysfunction, and menopause. Doctors may use fertility drugs, surgery, or assisted reproductive techniques (ART) in their therapy. ART involves the use of procedures to manipulate the egg or sperm to facilitate reproduction, such as *in vitro* fertilization.

Reproductive endocrinologists undergo extensive medical training, first in a four-year residency in obstetrics and gynecology, then in a three-year fellowship in reproductive endocrinology. To be board certified in this area, the physician must pass written and oral exams in both areas.

## 34.5 | Fertilization and Early Embryonic Development

In this section, you will explore the following questions:

- How does fertilization occur?
- How does the embryo form from the zygote?
- What are the roles of cleavage and fertilization in animal development?

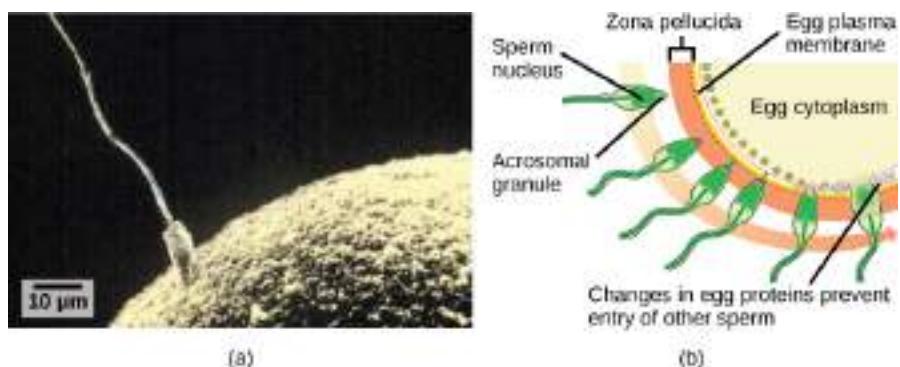

### Connection for AP<sup>®</sup> Courses

The information in this section is not within the scope for AP<sup>®</sup> other than to note that the process by which an organism develops from a single-celled zygote to a multi-cellular organism with specialized cells, tissues, and organs is complex and well regulated. The organization into a multi-cellular organism is regulated by an organism's genes. Cell differentiation is a result of specific gene expression, and homeotic (*HOX*) genes and morphogens control the pattern and timing of developmental stages.

Information presented and examples highlighted in this section are not within the scope for AP<sup>®</sup> and do not align to the Curriculum Framework.

### Fertilization

Fertilization, pictured in **Figure 34.20a** is the process in which gametes (an egg and sperm) fuse to form a zygote. The egg and sperm each contain one set of chromosomes. To ensure that the offspring has only one complete diploid set of chromosomes, only one sperm must fuse with one egg. In mammals, the egg is protected by a layer of extracellular matrix consisting mainly of glycoproteins called the **zona pellucida**. When a sperm binds to the zona pellucida, a series of biochemical events, called the **acrosomal reactions**, take place. In placental mammals, the acrosome contains digestive enzymes that initiate the degradation of the glycoprotein matrix protecting the egg and allowing the sperm plasma membrane to fuse with the egg plasma membrane, as illustrated in **Figure 34.20b**. The fusion of these two membranes creates an opening through which the sperm nucleus is transferred into the ovum. The nuclear membranes of the egg and sperm break down and the two haploid genomes condense to form a diploid genome.

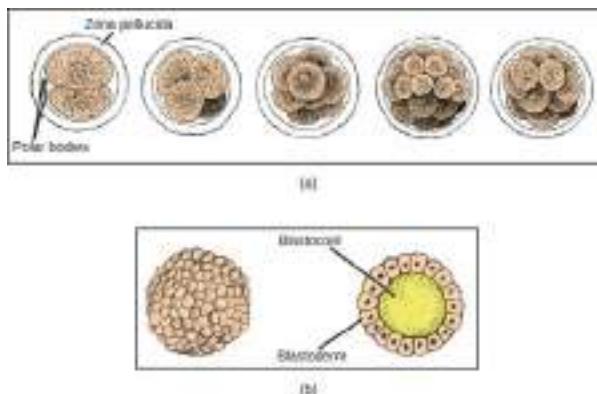

**Figure 34.20** (a) Fertilization is the process in which sperm and egg fuse to form a zygote. (b) Acrosomal reactions help the sperm degrade the glycoprotein matrix protecting the egg and allow the sperm to transfer its nucleus. (credit: (b) modification of work by Mariana Ruiz Villareal; scale-bar data from Matt Russell)

To ensure that no more than one sperm fertilizes the egg, once the acrosomal reactions take place at one location of the egg membrane, the egg releases proteins in other locations to prevent other sperm from fusing with the egg. If this mechanism fails, multiple sperm can fuse with the egg, resulting in **polyspermy**. The resulting embryo is not genetically viable and dies within a few days.

## Cleavage and Blastula Stage

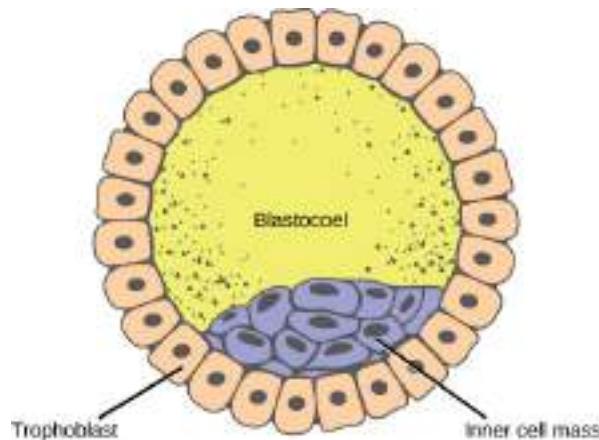

The development of multi-cellular organisms begins from a single-celled zygote, which undergoes rapid cell division to form the blastula. The rapid, multiple rounds of cell division are termed cleavage. Cleavage is illustrated in (Figure 34.21a). After the cleavage has produced over 100 cells, the embryo is called a blastula. The blastula is usually a spherical layer of cells (the blastoderm) surrounding a fluid-filled or yolk-filled cavity (the blastocoel). Mammals at this stage form a structure called the blastocyst, characterized by an inner cell mass that is distinct from the surrounding blastula, shown in Figure 34.21b. During cleavage, the cells divide without an increase in mass; that is, one large single-celled zygote divides into multiple smaller cells. Each cell within the blastula is called a blastomere.

**Figure 34.21** (a) During cleavage, the zygote rapidly divides into multiple cells without increasing in size. (b) The cells rearrange themselves to form a hollow ball with a fluid-filled or yolk-filled cavity called the blastula. (credit a: modification of work by Gray's Anatomy; credit b: modification of work by Pearson Scott Foresman, donated to the Wikimedia Foundation)

Cleavage can take place in two ways: **holoblastic** (total) cleavage or **meroblastic** (partial) cleavage. The type of cleavage depends on the amount of yolk in the eggs. In placental mammals (including humans) where nourishment is provided by the mother's body, the eggs have a very small amount of yolk and undergo holoblastic cleavage. Other species, such as birds, with a lot of yolk in the egg to nourish the embryo during development, undergo meroblastic cleavage.

In mammals, the blastula forms the **blastocyst** in the next stage of development. Here the cells in the blastula arrange themselves in two layers: the **inner cell mass**, and an outer layer called the **trophoblast**. The inner cell mass is also known as the embryoblast and this mass of cells will go on to form the embryo. At this stage of development, illustrated in Figure 34.22 the inner cell mass consists of embryonic stem cells that will differentiate into the different cell types needed by the organism. The trophoblast will contribute to the placenta and nourish the embryo.

**Figure 34.22** The rearrangement of the cells in the mammalian blastula to two layers—the inner cell mass and the trophoblast—results in the formation of the blastocyst.

Visit the **Virtual Human Embryo project** ([http://openstaxcollege.org/l/human\\_embryo](http://openstaxcollege.org/l/human_embryo)) at the Endowment for Human Development site to step through an interactive that shows the stages of embryo development, including micrographs and rotating 3-D images.

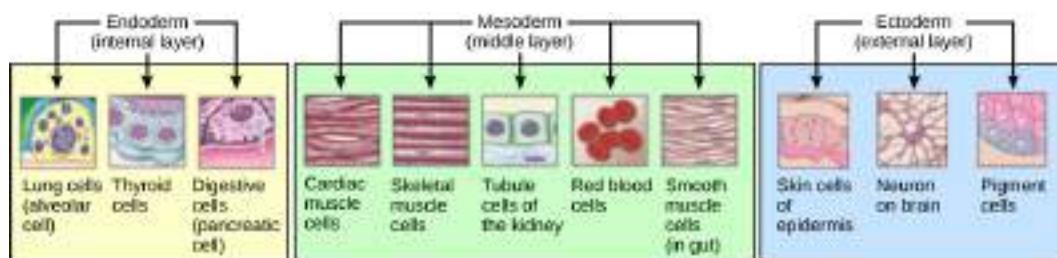

Which early embryonic stage is characterized by a fluid-filled cavity with an inner cell mass surrounded by a layer of cells?

- a. blastocyst
- b. blastula
- c. blastocoel
- d. gastrula

## Gastrulation

The typical blastula is a ball of cells. The next stage in embryonic development is the formation of the body plan. The cells in the blastula rearrange themselves spatially to form three layers of cells. This process is called **gastrulation**. During gastrulation, the blastula folds upon itself to form the three layers of cells. Each of these layers is called a germ layer and each germ layer differentiates into different organ systems.

The three germs layers, shown in **Figure 34.23**, are the endoderm, the ectoderm, and the mesoderm. The ectoderm gives rise to the nervous system and the epidermis. The mesoderm gives rise to the muscle cells and connective tissue in the body. The endoderm gives rise to columnar cells found in the digestive system and many internal organs.

**Figure 34.23** The three germ layers give rise to different cell types in the animal body. (credit: modification of work by NIH, NCBI)

# everyday CONNECTION

## Are Designer Babies in Our Future?

**Figure 34.24** This logo from the Second International Eugenics Conference in New York City in September of 1921 shows how eugenics attempted to merge several fields of study with the goal of producing a genetically superior human race.

If you could prevent your child from getting a devastating genetic disease, would you do it? Would you select the sex of your child or select for their attractiveness, strength, or intelligence? How far would you go to maximize the possibility of resistance to disease? The genetic engineering of a human child, the production of "designer babies" with desirable phenotypic characteristics, was once a topic restricted to science fiction. This is the case no longer: science fiction is now overlapping into science fact. Many phenotypic choices for offspring are already available, with many more likely to be possible in the not too distant future. Which traits should be selected and how they should be selected are topics of much debate within the worldwide medical community. The ethical and moral line is not always clear or agreed upon, and some fear that modern reproductive technologies could lead to a new form of eugenics.

Eugenics is the use of information and technology from a variety of sources to improve the genetic makeup of the human race. The goal of creating genetically superior humans was quite prevalent (although controversial) in several countries during the early 20<sup>th</sup> century, but fell into disrepute when Nazi Germany developed an extensive eugenics program in the 1930's and 40's. As part of their program, the Nazis forcibly sterilized hundreds of thousands of the so-called "unfit" and killed tens of thousands of institutionally disabled people as part of a systematic program to develop a genetically superior race of Germans known as Aryans. Ever since, eugenic ideas have not been as publicly expressed, but there are still those who promote them.

Efforts have been made in the past to control traits in human children using donated sperm from men with desired traits. In fact, eugenicist Robert Klark Graham established a sperm bank in 1980 that included samples exclusively from donors with high IQs. The "genius" sperm bank failed to capture the public's imagination and the operation closed in 1999.

In more recent times, the procedure known as prenatal genetic diagnosis (PGD) has been developed. PGD involves the screening of human embryos as part of the process of *in vitro* fertilization, during which embryos are conceived and grown outside the mother's body for some period of time before they are implanted. The term PGD usually refers to both the diagnosis, selection, and the implantation of the selected embryos.

In the least controversial use of PGD, embryos are tested for the presence of alleles which cause genetic diseases such as sickle cell disease, muscular dystrophy, and hemophilia, in which a single disease-causing allele or pair of alleles has been identified. By excluding embryos containing these alleles from implantation into the mother, the disease is prevented, and the unused embryos are either donated to science or discarded. There are relatively few in the worldwide medical community that question the ethics of this type

of procedure, which allows individuals scared to have children because of the alleles they carry to do so successfully. The major limitation to this procedure is its expense. Not usually covered by medical insurance and thus out of reach financially for most couples, only a very small percentage of all live births use such complicated methodologies. Yet, even in cases like these where the ethical issues may seem to be clear-cut, not everyone agrees with the morality of these types of procedures. For example, to those who take the position that human life begins at conception, the discarding of unused embryos, a necessary result of PGD, is unacceptable under any circumstances.

A murkier ethical situation is found in the selection of a child's sex, which is easily performed by PGD. Currently, countries such as Great Britain have banned the selection of a child's sex for reasons other than preventing sex-linked diseases. Other countries allow the procedure for "family balancing", based on the desire of some parents to have at least one child of each sex. Still others, including the United States, have taken a scattershot approach to regulating these practices, essentially leaving it to the individual practicing physician to decide which practices are acceptable and which are not.

Even murkier are rare instances of disabled parents, such as those with deafness or dwarfism, who select embryos via PGD to ensure that they share their disability. These parents usually cite many positive aspects of their disabilities and associated culture as reasons for their choice, which they see as their moral right. To others, to purposely cause a disability in a child violates the basic medical principle of *Primum non nocere*, "first, do no harm." This procedure, although not illegal in most countries, demonstrates the complexity of ethical issues associated with choosing genetic traits in offspring.

Where could this process lead? Will this technology become more affordable and how should it be used? With the ability of technology to progress rapidly and unpredictably, a lack of definitive guidelines for the use of reproductive technologies before they arise might make it difficult for legislators to keep pace once they are in fact realized, assuming the process needs any government regulation at all. Other bioethicists argue that we should only deal with technologies that exist now, and not in some uncertain future. They argue that these types of procedures will always be expensive and rare, so the fears of eugenics and "master" races are unfounded and overstated. The debate continues.

Prenatal genetic diagnosis (PGD) is often sought by parents before an embryo is implanted in the mother. Which of the following CANNOT be diagnosed by PGD?

- a. inheritance of sickle cell anemia
- b. Down's syndrome
- c. determination of sex
- d. inheritance of sexually transmitted diseases

## 34.6 | Organogenesis and Vertebrate Formation

In this section, you will explore the following questions:

- What are the stages in the process of organogenesis in vertebrate animals?
- What are the anatomical axes in vertebrates and their significance in development?

### Connection for AP<sup>®</sup> Courses

The information in this section is not within the scope of AP<sup>®</sup>. The formation of organs from embryonic germ layers results from the expression of specific sets of genes that determine cell type. **Organogenesis** has been studied in the laboratory using the fruit fly (*Drosophila*) and the nematode *Caenorhabditis elegans*. In vertebrates, one of the primary steps during organogenesis is the formation of the neural system from embryonic ectoderm. Formation of body axes (lateral-medial, dorsal-ventral, and anterior-posterior) is another important developmental stage under genetic control.

Information presented and examples highlighted in this section are not within the scope for AP<sup>®</sup> and do not align to the Curriculum Framework.

Gastrulation leads to the formation of the three germ layers that give rise, during further development, to the different organs

in the animal body. This process is called organogenesis. Organogenesis is characterized by rapid and precise movements of the cells within the embryo.

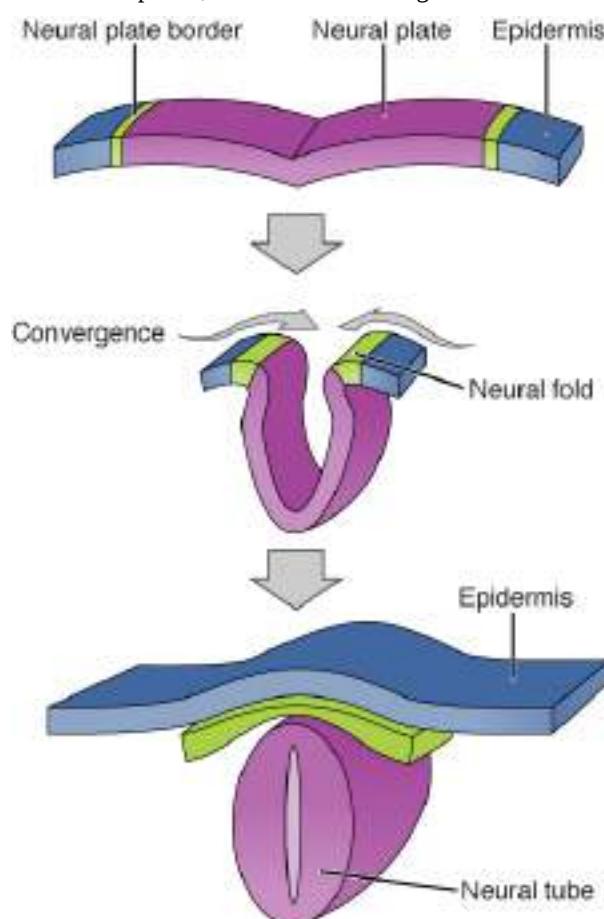

## Organogenesis

Organs form from the germ layers through the process of differentiation. During differentiation, the embryonic stem cells express specific sets of genes which will determine their ultimate cell type. For example, some cells in the ectoderm will express the genes specific to skin cells. As a result, these cells will differentiate into epidermal cells. The process of differentiation is regulated by cellular signaling cascades.

Scientists study organogenesis extensively in the lab in fruit flies (*Drosophila*) and the nematode *Caenorhabditis elegans*. *Drosophila* have segments along their bodies, and the patterning associated with the segment formation has allowed scientists to study which genes play important roles in organogenesis along the length of the embryo at different time points. The nematode *C. elegans* has roughly 1000 somatic cells and scientists have studied the fate of each of these cells during their development in the nematode life cycle. There is little variation in patterns of cell lineage between individuals, unlike in mammals where cell development from the embryo is dependent on cellular cues.

In vertebrates, one of the primary steps during organogenesis is the formation of the neural system. The ectoderm forms epithelial cells and tissues, and neuronal tissues. During the formation of the neural system, special signaling molecules called growth factors signal some cells at the edge of the ectoderm to become epidermis cells. The remaining cells in the center form the neural plate. If the signaling by growth factors were disrupted, then the entire ectoderm would differentiate into neural tissue.

The neural plate undergoes a series of cell movements where it rolls up and forms a tube called the **neural tube**, as illustrated in **Figure 34.25**. In further development, the neural tube will give rise to the brain and the spinal cord.

**Figure 34.25** The central region of the ectoderm forms the neural tube, which gives rise to the brain and the spinal cord.

The mesoderm that lies on either side of the vertebrate neural tube will develop into the various connective tissues of the animal body. A spatial pattern of gene expression reorganizes the mesoderm into groups of cells called **somites** with spaces

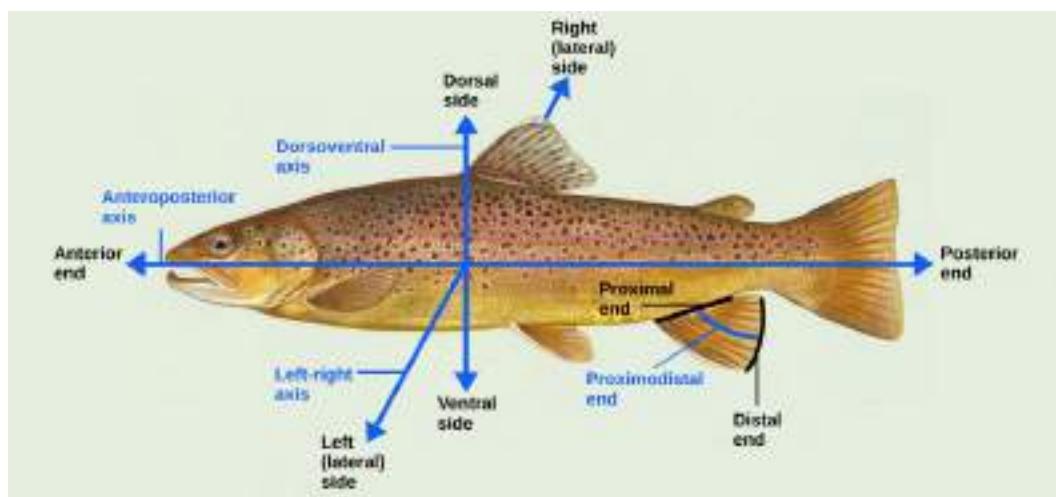

between them. The somites, illustrated in **Figure 34.26** will further develop into the ribs, lungs, and segmental (spine) muscle. The mesoderm also forms a structure called the notochord, which is rod-shaped and forms the central axis of the animal body.

**Figure 34.26** In this five-week old human embryo, somites are segments along the length of the body. (credit: modification of work by Ed Uthman)

## Vertebrate Axis Formation

Even as the germ layers form, the ball of cells still retains its spherical shape. However, animal bodies have lateral-medial (left-right), dorsal-ventral (back-belly), and anterior-posterior (head-feet) axes, illustrated in **Figure 34.27**.

**Figure 34.27** Animal bodies have three axes for symmetry. (credit: modification of work by NOAA)

How are these established? In one of the most seminal experiments ever to be carried out in developmental biology, Spemann and Mangold took dorsal cells from one embryo and transplanted them into the belly region of another embryo. They found that the transplanted embryo now had two notochords: one at the dorsal site from the original cells and another at the transplanted site. This suggested that the dorsal cells were genetically programmed to form the notochord and define the axis. Since then, researchers have identified many genes that are responsible for axis formation. Mutations in these genes leads to the loss of symmetry required for organism development.

Animal bodies have externally visible symmetry. However, the internal organs are not symmetric. For example, the heart is on the left side and the liver on the right. The formation of the central left-right axis is an important process during

development. This internal asymmetry is established very early during development and involves many genes. Research is still ongoing to fully understand the developmental implications of these genes.

## 34.7 | Human Pregnancy and Birth

In this section, you will explore the following questions:

- What are the stages of fetal development during the first three trimesters of gestation?
- What are the events in labor and delivery?
- What are the efficacy and duration of various types of contraception?
- What are causes of infertility and the therapeutic options available?

### Connection for AP® Courses

The information in this section is not within the scope for AP®, and you likely studied this information in a prior health class. However, if you are unfamiliar with the material, now is the time to learn it. Not only is the material interesting and informative, it is practical and relevant to any person of reproductive age, including high school students in an AP® course.

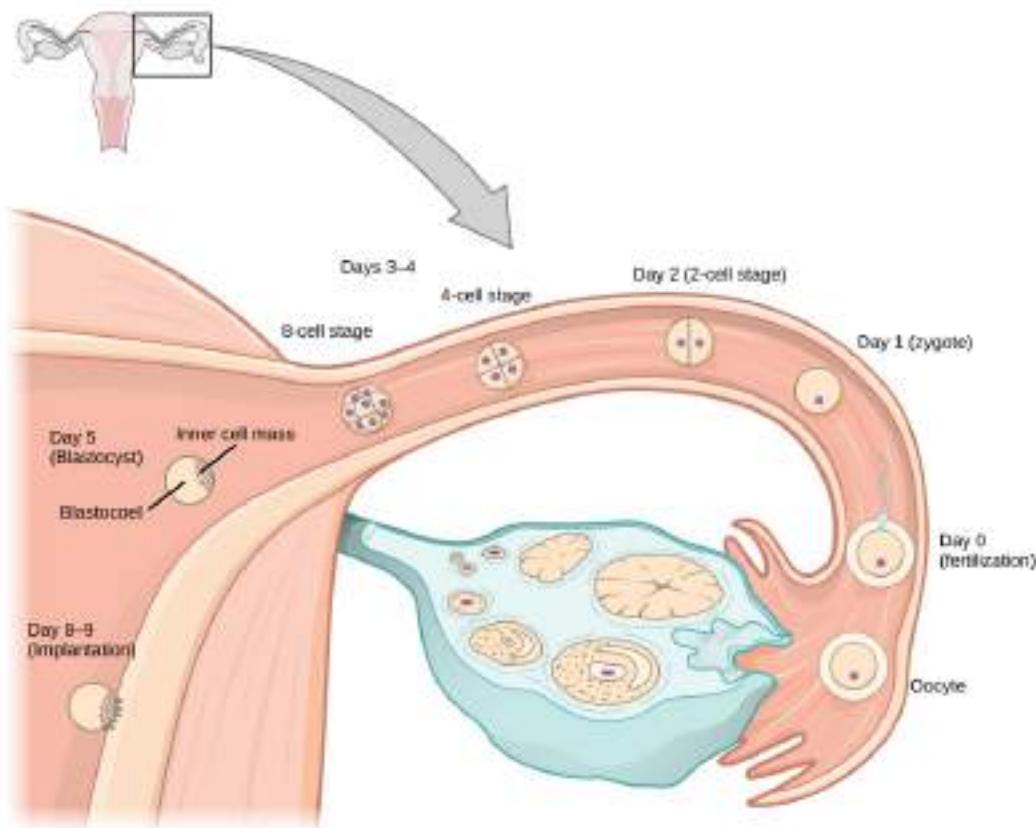

Pregnancy begins with the fertilization of an egg and continues through the birth of the individual. The length of time of **gestation** in animals varies, from 60 days in dogs and cats to 266 days in humans. The prevention of pregnancy occurs under the terms of contraception or birth control. Because knowledge of the endocrine systems and how hormones work is required for AP®, the information in the section about hormonal methods of contraception, such as birth control, is especially applicable.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

|                                   |                                                                                                                                       |

| <b>Big Idea 2</b>                 | Biological systems utilize free energy and molecular building blocks to grow, to reproduce, and to maintain dynamic homeostasis.      |
| <b>Enduring Understanding 2.C</b> | Organisms use feedback mechanisms to regulate growth and reproduction, and to maintain dynamic homeostasis.                           |
| <b>Essential Knowledge</b>        | <b>2.C.1</b> Organisms use feedback mechanisms to maintain their internal environments and respond to external environmental changes. |
| <b>Science Practice</b>           | <b>6.1</b> The student can justify claims with evidence.                                                                              |
| <b>Learning Objective</b>         | <b>2.20</b> The student is able to justify that positive feedback mechanisms amplify responses in organisms.                          |

### Human Gestation

Twenty-four hours before fertilization, the egg has finished meiosis and becomes a mature oocyte. When fertilized (at conception) the egg becomes known as a zygote. The zygote travels through the oviduct to the uterus ([Figure 34.28](#)). The developing embryo must implant into the wall of the uterus within seven days, or it will deteriorate and die. The outer layers of the zygote (blastocyst) grow into the endometrium by digesting the endometrial cells, and wound healing of the endometrium closes up the blastocyst into the tissue. Another layer of the blastocyst, the chorion, begins releasing a hormone called **human beta chorionic gonadotropin (β-HCG)** which makes its way to the corpus luteum and keeps that structure active. This ensures adequate levels of progesterone that will maintain the endometrium of the uterus for the support of the developing embryo. Pregnancy tests determine the level of β-HCG in urine or serum. If the hormone is present, the test is positive.

**Figure 34.28** In humans, fertilization occurs soon after the oocyte leaves the ovary. Implantation occurs eight or nine days later. (credit: Ed Uthman)

The gestation period is divided into three equal periods or trimesters. During the first two to four weeks of the first trimester, nutrition and waste are handled by the endometrial lining through diffusion. As the trimester progresses, the outer layer of the embryo begins to merge with the endometrium, and the **placenta** forms. This organ takes over the nutrient and waste requirements of the embryo and fetus, with the mother's blood passing nutrients to the placenta and removing waste from it. Chemicals from the fetus, such as bilirubin, are processed by the mother's liver for elimination. Some of the mother's immunoglobulins will pass through the placenta, providing passive immunity against some potential infections.

Internal organs and body structures begin to develop during the first trimester. By five weeks, limb buds, eyes, the heart, and liver have been basically formed. By eight weeks, the term fetus applies, and the body is essentially formed, as shown in **Figure 34.29**. The individual is about five centimeters (two inches) in length and many of the organs, such as the lungs and liver, are not yet functioning. Exposure to any toxins is especially dangerous during the first trimester, as all of the body's organs and structures are going through initial development. Anything that affects that development can have a severe effect on the fetus' survival.

**Figure 34.29** Fetal development is shown at nine weeks gestation. (credit: Ed Uthman)

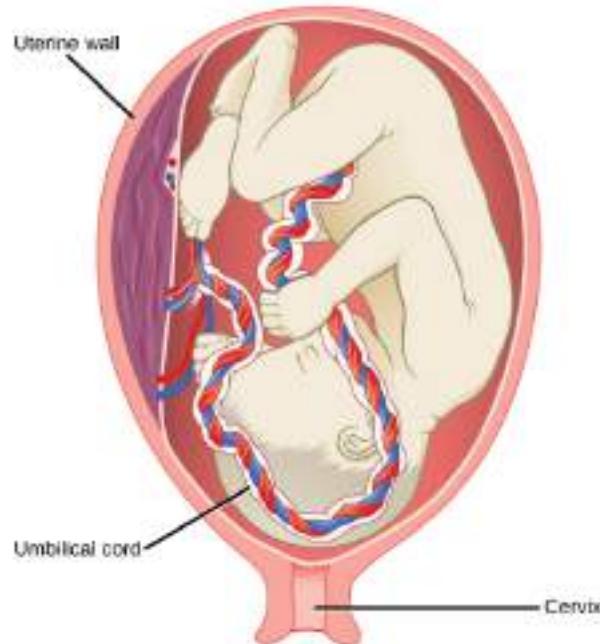

During the second trimester, the fetus grows to about 30 cm (12 inches), as shown in **Figure 34.30**. It becomes active and the mother usually feels the first movements. All organs and structures continue to develop. The placenta has taken over the functions of nutrition and waste and the production of estrogen and progesterone from the corpus luteum, which has degenerated. The placenta will continue functioning up through the delivery of the baby.

**Figure 34.30** This fetus is just entering the second trimester, when the placenta takes over more of the functions performed as the baby develops. (credit: National Museum of Health and Medicine)

During the third trimester, the fetus grows to 3 to 4 kg (6 ½ -8 ½ lbs.) and about 50 cm (19-20 inches) long, as illustrated in **Figure 34.31**. This is the period of the most rapid growth during the pregnancy. Organ development continues to birth (and some systems, such as the nervous system and liver, continue to develop after birth). The mother will be at her most

uncomfortable during this trimester. She may urinate frequently due to pressure on the bladder from the fetus. There may also be intestinal blockage and circulatory problems, especially in her legs. Clots may form in her legs due to pressure from the fetus on returning veins as they enter the abdominal cavity.

**Figure 34.31** There is rapid fetal growth during the third trimester. (credit: modification of work by Gray's Anatomy)

Visit **this site** ([http://openstaxcollege.org/l/embryo\\_fetus](http://openstaxcollege.org/l/embryo_fetus)) to see the stages of human fetal development.

In humans, by which week of gestation are all limbs and essential organs formed?

- a. 5
- b. 6
- c. 7
- d. 8

## Labor and Birth

Labor is the physical efforts of expulsion of the fetus and the placenta from the uterus during birth (parturition). Toward the end of the third trimester, estrogen causes receptors on the uterine wall to develop and bind the hormone oxytocin. At this time, the baby reorients, facing forward and down with the back or crown of the head engaging the cervix (uterine opening). This causes the cervix to stretch and nerve impulses are sent to the hypothalamus, which signals for the release of oxytocin from the posterior pituitary. The oxytocin causes the smooth muscle in the uterine wall to contract. At the same time, the placenta releases prostaglandins into the uterus, increasing the contractions. A positive feedback relay occurs between the uterus, hypothalamus, and the posterior pituitary to assure an adequate supply of oxytocin. As more smooth muscle cells are recruited, the contractions increase in intensity and force.

There are three stages to labor. During stage one, the cervix thins and dilates. This is necessary for the baby and placenta to be expelled during birth. The cervix will eventually dilate to about 10 cm. During stage two, the baby is expelled from the uterus. The uterus contracts and the mother pushes as she compresses her abdominal muscles to aid the delivery. The last stage is the passage of the placenta after the baby has been born and the organ has completely disengaged from the uterine wall. If labor should stop before stage two is reached, synthetic oxytocin can be administered to restart and maintain labor.

An alternative to labor and delivery is the surgical delivery of the baby through a procedure called a Caesarian section. This is major abdominal surgery and can lead to post-surgical complications for the mother, but in some cases it may be the only way to safely deliver the baby.

The mother's mammary glands go through changes during the third trimester to prepare for lactation and breastfeeding. When the baby begins suckling at the breast, signals are sent to the hypothalamus causing the release of prolactin from the anterior pituitary. Prolactin causes the mammary glands to produce milk. Oxytocin is also released, promoting the release of the milk. The milk contains nutrients for the baby's development and growth as well as immunoglobulins to protect the child from bacterial and viral infections.

## Contraception and Birth Control

The prevention of a pregnancy comes under the terms contraception or birth control. Strictly speaking, **contraception** refers to preventing the sperm and egg from joining. Both terms are, however, frequently used interchangeably.

### Contraceptive Methods

| Method   | Examples                                                                 | Failure Rate in Typical Use Over 12 Months |
|----------|--------------------------------------------------------------------------|--------------------------------------------|
| Barrier  | male condom, female condom, sponge, cervical cap, diaphragm, spermicides | 15 to 24%                                  |
| Hormonal | oral, patch, vaginal ring                                                | 8%                                         |
|          | injection                                                                | 3%                                         |
|          | implant                                                                  | less than 1%                               |
| Other    | natural family planning                                                  | 12 to 25%                                  |
|          | withdrawal                                                               | 27%                                        |
|          | sterilization                                                            | less than 1%                               |

**Table 34.3**

**Table 34.3** lists common methods of contraception. The failure rates listed are not the ideal rates that could be realized, but the typical rates that occur. A failure rate is the number of pregnancies resulting from the method's use over a twelve-month period. Barrier methods, such as condoms, cervical caps, and diaphragms, block sperm from entering the uterus, preventing fertilization. Spermicides are chemicals that are placed in the vagina that kill sperm. Sponges, which are saturated with spermicides, are placed in the vagina at the cervical opening. Combinations of spermicidal chemicals and barrier methods achieve lower failure rates than do the methods when used separately.

Nearly a quarter of the couples using barrier methods, natural family planning, or withdrawal can expect a failure of the method. Natural family planning is based on the monitoring of the menstrual cycle and having intercourse only during times when the egg is not available. A woman's body temperature may rise a degree Celsius at ovulation and the cervical mucus may increase in volume and become more pliable. These changes give a general indication of when intercourse is more or less likely to result in fertilization. Withdrawal involves the removal of the penis from the vagina during intercourse, before ejaculation occurs. This is a risky method with a high failure rate due to the possible presence of sperm in the bulbourethral gland's secretion, which may enter the vagina prior to removing the penis.

Hormonal methods use synthetic progesterone (sometimes in combination with estrogen), to inhibit the hypothalamus from releasing FSH or LH, and thus prevent an egg from being available for fertilization. The method of administering the hormone affects failure rate. The most reliable method, with a failure rate of less than 1 percent, is the implantation of the hormone under the skin. The same rate can be achieved through the sterilization procedures of vasectomy in the man or of tubal ligation in the woman, or by using an intrauterine device (IUD). IUDs are inserted into the uterus and establish an inflammatory condition that prevents fertilized eggs from implanting into the uterine wall.

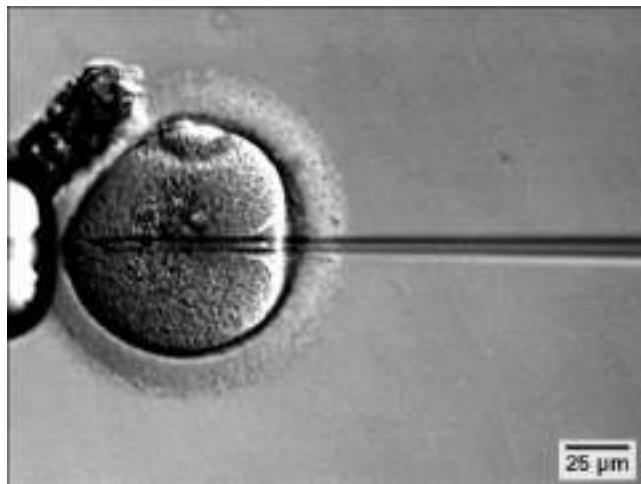

Compliance with the contraceptive method is a strong contributor to the success or failure rate of any particular method. The only method that is completely effective at preventing conception is abstinence. The choice of contraceptive method depends on the goals of the woman or couple. Tubal ligation and vasectomy are considered permanent prevention, while other methods are reversible and provide short-term contraception.

Termination of an existing pregnancy can be spontaneous or voluntary. Spontaneous termination is a miscarriage and usually occurs very early in the pregnancy, usually within the first few weeks. This occurs when the fetus cannot develop properly and the gestation is naturally terminated. Voluntary termination of a pregnancy is an abortion. Laws regulating abortion vary between states and tend to view fetal viability as the criteria for allowing or preventing the procedure.

## Infertility

**Infertility** is the inability to conceive a child or carry a child to birth. About 75 percent of causes of infertility can be identified; these include diseases, such as sexually transmitted diseases that can cause scarring of the reproductive tubes in either men or women, or developmental problems frequently related to abnormal hormone levels in one of the individuals. Inadequate nutrition, especially starvation, can delay menstruation. Stress can also lead to infertility. Short-term stress can affect hormone levels, while long-term stress can delay puberty and cause less frequent menstrual cycles. Other factors that affect fertility include toxins (such as cadmium), tobacco smoking, marijuana use, gonadal injuries, and aging.

If infertility is identified, several assisted reproductive technologies (ART) are available to aid conception. A common type of ART is *in vitro* fertilization (IVF) where an egg and sperm are combined outside the body and then placed in the uterus. Eggs are obtained from the woman after extensive hormonal treatments that prepare mature eggs for fertilization and prepare the uterus for implantation of the fertilized egg. Sperm are obtained from the man and they are combined with the eggs and supported through several cell divisions to ensure viability of the zygotes. When the embryos have reached the eight-cell stage, one or more is implanted into the woman's uterus. If fertilization is not accomplished by simple IVF, a procedure that injects the sperm into an egg can be used. This is called intracytoplasmic sperm injection (ICSI) and is shown in [Figure 34.32](#). IVF procedures produce a surplus of fertilized eggs and embryos that can be frozen and stored for future use. The procedures can also result in multiple births.

**Figure 34.32** A sperm is inserted into an egg for fertilization during intracytoplasmic sperm injection (ICSI). (credit: scale-bar data from Matt Russell)

## KEY TERMS

- acrosomal reaction** series of biochemical reactions that the sperm uses to break through the zona pellucida
- amniote** an organism whose embryo develops within a shelled egg with extraembryonic membranes
- asexual reproduction** form of reproduction that produces offspring that are genetically identical to the parent
- blastocyst** structure formed when cells in the mammalian blastula separate into an inner and outer layer
- budding** form of asexual reproduction that results from the outgrowth of a part of a cell leading to a separation from the original animal into two individuals
- bulbourethral gland** secretion that cleanses the urethra prior to ejaculation
- clitoris** sensory structure in females; stimulated during sexual arousal
- cloaca** common body opening for the digestive, excretory, and reproductive systems found in non-mammals, such as birds
- contraception** (also, birth control) various means used to prevent pregnancy
- estrogen** reproductive hormone in females that assists in endometrial regrowth, ovulation, and calcium absorption
- external fertilization** fertilization of egg by sperm outside animal body, often during spawning
- fission** (also, binary fission) method by which multicellular organisms increase in size or asexual reproduction in which a unicellular organism splits into two separate organisms by mitosis
- follicle stimulating hormone (FSH)** reproductive hormone that causes sperm production in men and follicle development in women
- fragmentation** cutting or fragmenting of the original animal into parts and the growth of a separate animal from each part
- gastrulation** process in which the blastula folds over itself to form the three germ layers
- gestation** length of time for fetal development to birth
- gonadotropin-releasing hormone (GnRH)** hormone from the hypothalamus that causes the release of FSH and LH from the anterior pituitary
- hermaphroditism** state of having both male and female reproductive parts within the same individual
- holoblastic** complete cleavage; takes place in cells with a small amount of yolk
- human beta chorionic gonadotropin ( $\beta$ -HCG)** hormone produced by the chorion of the zygote that helps to maintain the corpus luteum and elevated levels of progesterone
- infertility** inability to conceive, carry, and deliver children
- inhibin** hormone made by Sertoli cells; provides negative feedback to hypothalamus in control of FSH and GnRH release
- inner cell mass** inner layer of cells in the blastocyst
- internal fertilization** fertilization of egg by sperm inside the body of the female
- interstitial cell of Leydig** cell in seminiferous tubules that makes testosterone
- labia majora** large folds of tissue covering the inguinal area
- labia minora** smaller folds of tissue within the labia majora
- luteinizing hormone (LH)** reproductive hormone in both men and women, causes testosterone production in men and ovulation and lactation in women

**menopause** loss of reproductive capacity in women due to decreased sensitivity of the ovaries to FSH and LH

**menstrual cycle** cycle of the degradation and re-growth of the endometrium

**meroblastic** partial cleavage; takes place in cells with a large amount of yolk

**morning sickness** condition in the mother during the first trimester; includes feelings of nausea

**neural tube** tube-like structure that forms from the ectoderm and gives rise to the brain and spinal cord

**oogenesis** process of producing haploid eggs

**organogenesis** process of organ formation

**ovarian cycle** cycle of preparation of egg for ovulation and the conversion of the follicle to the corpus luteum

**oviduct** (also, fallopian tube) muscular tube connecting the uterus with the ovary area

**oviparity** process by which fertilized eggs are laid outside the female's body and develop there, receiving nourishment from the yolk that is a part of the egg

**ovoviparity** process by which fertilized eggs are retained within the female; the embryo obtains its nourishment from the egg's yolk and the young are fully developed when they are hatched

**ovulation** release of the egg by the most mature follicle

**parthenogenesis** form of asexual reproduction where an egg develops into a complete individual without being fertilized

**penis** male reproductive structure for urine elimination and copulation

**placenta** organ that supports the diffusion of nutrients and waste between the mother's and fetus' blood

**polyspermy** condition in which one egg is fertilized by multiple sperm

**progesterone** reproductive hormone in women; assists in endometrial re-growth and inhibition of FSH and LH release

**prostate gland** structure that is a mixture of smooth muscle and glandular material and that contributes to semen

**scrotum** sac containing testes; exterior to the body

**semen** fluid mixture of sperm and supporting materials

**seminal vesicle** secretory accessory gland in males; contributes to semen

**seminiferous tubule** site of sperm production in testes

**Sertoli cell** cell in seminiferous tubules that assists developing sperm and makes inhibin

**sexual reproduction** mixing of genetic material from two individuals to produce genetically unique offspring

**somite** group of cells separated by small spaces that form from the mesoderm and give rise to connective tissue

**spermatheca** specialized sac that stores sperm for later use

**spermatogenesis** process of producing haploid sperm

**testes** pair of reproductive organs in males

**testosterone** reproductive hormone in men that assists in sperm production and promoting secondary sexual characteristics

**trophoblast** outer layer of cells in the blastocyst

**uterus** environment for developing embryo and fetus

**vagina** muscular tube for the passage of menstrual flow, copulation, and birth of offspring

**viviparity** process in which the young develop within the female, receiving nourishment from the mother's blood through a placenta

**zona pellucida** protective layer of glycoproteins on the mammalian egg

## CHAPTER SUMMARY

### 34.1 Reproduction Methods

Reproduction may be asexual when one individual produces genetically identical offspring, or sexual when the genetic material from two individuals is combined to produce genetically diverse offspring. Asexual reproduction occurs through fission, budding, and fragmentation. Sexual reproduction may mean the joining of sperm and eggs within animals' bodies or it may mean the release of sperm and eggs into the environment. An individual may be one sex, or both; it may start out as one sex and switch during its life, or it may stay male or female.

### 34.2 Fertilization

Sexual reproduction starts with the combination of a sperm and an egg in a process called fertilization. This can occur either outside the bodies or inside the female. Both methods have advantages and disadvantages. Once fertilized, the eggs can develop inside the female or outside. If the egg develops outside the body, it usually has a protective covering over it. Animal anatomy evolved various ways to fertilize, hold, or expel the egg. The method of fertilization varies among animals. Some species release the egg and sperm into the environment, some species retain the egg and receive the sperm into the female body and then expel the developing embryo covered with shell, while still other species retain the developing offspring through the gestation period.

### 34.3 Human Reproductive Anatomy and Gametogenesis

As animals became more complex, specific organs and organ systems developed to support specific functions for the organism. The reproductive structures that evolved in land animals allow males and females to mate, fertilize internally, and support the growth and development of offspring. Processes developed to produce reproductive cells that had exactly half the number of chromosomes of each parent so that new combinations would have the appropriate amount of genetic material. Gametogenesis, the production of sperm (spermatogenesis) and eggs (oogenesis), takes place through the process of meiosis.

### 34.4 Hormonal Control of Human Reproduction

The male and female reproductive cycles are controlled by hormones released from the hypothalamus and anterior pituitary as well as hormones from reproductive tissues and organs. The hypothalamus monitors the need for the FSH and LH hormones made and released from the anterior pituitary. FSH and LH affect reproductive structures to cause the formation of sperm and the preparation of eggs for release and possible fertilization. In the male, FSH and LH stimulate Sertoli cells and interstitial cells of Leydig in the testes to facilitate sperm production. The Leydig cells produce testosterone, which also is responsible for the secondary sexual characteristics of males. In females, FSH and LH cause estrogen and progesterone to be produced. They regulate the female reproductive system which is divided into the ovarian cycle and the menstrual cycle. Menopause occurs when the ovaries lose their sensitivity to FSH and LH and the female reproductive cycles slow to a stop.

### 34.5 Fertilization and Early Embryonic Development

The early stages of embryonic development begin with fertilization. The process of fertilization is tightly controlled to ensure that only one sperm fuses with one egg. After fertilization, the zygote undergoes cleavage to form the blastula. The blastula, which in some species is a hollow ball of cells, undergoes a process called gastrulation, in which the three germ layers form. The ectoderm gives rise to the nervous system and the epidermal skin cells, the mesoderm gives rise to the muscle cells and connective tissue in the body, and the endoderm gives rise to columnar cells and internal organs.

### 34.6 Organogenesis and Vertebrate Formation

Organogenesis is the formation of organs from the germ layers. Each germ layer gives rise to specific tissue types. The

first stage is the formation of the neural system in the ectoderm. The mesoderm gives rise to somites and the notochord. Formation of vertebrate axis is another important developmental stage.

### 34.7 Human Pregnancy and Birth

Human pregnancy begins with fertilization of an egg and proceeds through the three trimesters of gestation. The labor process has three stages (contractions, delivery of the fetus, expulsion of the placenta), each propelled by hormones. The first trimester lays down the basic structures of the body, including the limb buds, heart, eyes, and the liver. The second trimester continues the development of all of the organs and systems. The third trimester exhibits the greatest growth of the fetus and culminates in labor and delivery. Prevention of a pregnancy can be accomplished through a variety of methods including barriers, hormones, or other means. Assisted reproductive technologies may help individuals who have infertility problems.

## REVIEW QUESTIONS

1. Which method of reproduction produces identical offspring and is most successful in a stable environment?
  - a. asexual reproduction
  - b. sexual
  - c. conjugation
  - d. inbreeding
2. Which method produces genetically-unique offspring?
  - a. parthenogenesis
  - b. budding
  - c. fragmentation
  - d. sexual reproduction
3. Which of the following statements is false?
  - a. Budding is a method of asexual reproduction.
  - b. Fragmentation is a method of asexual reproduction.
  - c. Parthenogenesis is a type of sexual reproduction that produces diverse offspring.
  - d. Binary fission is a method of asexual reproduction.
4. Sea stars are broken apart by workers to save the clams they feed on, and then thrown back into the ocean. Often the numbers of sea stars are seen to double after this. Give the reason why this happens.
  - a. regeneration
  - b. fragmentation
  - c. budding
  - d. the presence of suitable conditions
5. Which form of reproduction might be utilized by a sexually reproducing animal that has limited mobility?
  - a. fragmentation
  - b. budding
  - c. hermaphroditism
  - d. parthenogenesis
6. In sexual reproduction, gametes with either an X or Y chromosome are formed in males, whereas gametes in females contain a single X chromosome. What is the nature of both male and female gametes?
  - a. diploid
  - b. haploid
  - c. homozygous
  - d. heterozygous
7. External fertilization most commonly occurs in which type of environment?
  - a. aquatic
  - b. forests
  - c. savanna
  - d. steppe
8. Why is broadcast spawning considered advantageous?
  - a. Production of many eggs increases the chance of fertilization.
  - b. Production of many sperm increases the chance of fertilization.
  - c. It results in mixing of genes and greater genetic diversity.
  - d. Animals that are motile carry out this process.
9. Which term applies to egg development outside the female with nourishment derived from a yolk?
  - a. oviparity
  - b. viviparity
  - c. ovoviparity
  - d. ovoviparity
10. How are the offspring of viviparous animals different from the offspring of oviparous animals?

- a. They are protected from the external environment.  
 b. They are produced in higher numbers.  
 c. They can live longer.  
 d. They can utilize nutrients better.
- 11.** Which of the following structures is involved in mating in birds?
- cloaca
  - spermatheca
  - uterus
  - coelom
- 12.** The spermatheca, which is found in many insects, worms, and mollusks, is useful for \_\_\_\_\_.  
 a. spermatogenesis  
 b. sperm motility  
 c. growth of embryos  
 d. storing sperm and as a site for fertilization
- 13.** Which part of the male reproductive system produces most of the semen?  
 a. scrotum  
 b. seminal vesicles  
 c. seminiferous tubules  
 d. prostate gland
- 14.** How is an oocyte released from a human ovary so it can enter the oviduct?  
 a. the beating action of the flagellum on the oocyte  
 b. the force of the follicular ejection directing the oocyte into the oviduct  
 c. the wavelike beating of cilia lining the oviduct  
 d. muscular contraction of the ovaries
- 15.** Which female organ has the same embryonic origin as the penis?  
 a. clitoris  
 b. labia majora  
 c. greater vestibular glands  
 d. vagina
- 16.** Which structure is only related to the male urinary system, as opposed to the male reproductive system?  
 a. urinary bladder  
 b. cowper's gland  
 c. bulbourethral gland  
 d. urethra
- 17.** How many eggs are produced as a result of one meiotic series of cell divisions?  
 a. 1  
 b. 2  
 c. 3  
 d. 4
- 18.** Which of the following events activate the germ cells at puberty to produce spermatozoa?  
 a. activation by gonadotropin-releasing hormone  
 b. activation by increased hair growth  
 c. increase in blood volume  
 d. increase of secretion of testosterone
- 19.** What stimulates Leydig cells in the testes to produce testosterone?  
 a. FSH  
 b. LH  
 c. inhibin  
 d. estrogen
- 20.** In both males and females, the hormones FSH and LH play a critical role in the reproductive phase. What regulates the secretion of these hormones?  
 a. GnRH  
 b. estrogen  
 c. progesterone  
 d. inhibin
- 21.** Which hormone prepares the endometrial lining of the uterus for potential implantation?  
 a. testosterone  
 b. estrogen  
 c. GnRH  
 d. progesterone
- 22.** With the onset of menopause, the follicles stop responding to which of the following hormones?  
 a. estradiol and progesterone  
 b. progesterone and estrogen  
 c. FSH and LH  
 d. FSH and GnRH
- 23.** After ovulation, increasing amounts of \_\_\_\_\_ cause the endometrium to start to thicken.  
 a. fluid  
 b. LH  
 c. progesterone  
 d. GnRH
- 24.** What characterizes the acrosomal reactions?

- a. The sperm degrades the outermost layer of the egg to penetrate it.
- b. motility of the sperm
- c. fusion of the egg and sperm
- d. breakdown of the envelope covering the sperm head
25. What occurs as a result of fertilization of an egg and sperm?
- Fertilization restores diploidy.
  - Fertilization always results in a viable embryo.
  - Fertilization merges two diploid cells into a haploid cell.
  - Fertilization precedes ovulation.
26. Which of the following statements regarding early embryonic stages is false?
- The endoderm, mesoderm, and ectoderm are germ layers.
  - The trophoblast is a germ layer.
  - The inner cell mass is a source of embryonic stem cells.
  - The blastula is often a hollow ball of cells.
27. Gastrulation is the process in which the cells in the blastula rearrange themselves and form three layers of cells. Each layer will differentiate into a different organ system. At what point of development do the major organs begin to develop?
- fertilization
  - first trimester
  - second trimester
  - third trimester
28. What happens to the number of cells during cleavage?
- increases
  - decreases
  - doubles with every cell division
  - does not change significantly
29. The blastula stage is a mass of specialized cells. Of the following, which forms the liver cells?
- inner cell mass
  - trophoblast
  - blastula
  - blastomere
30. Which germ layer forms the skin cells?
- a. endoderm
- b. ectoderm
- c. mesoderm
- d. trophoblast
31. What are the three phases of embryonic development in chronological order?
- blastula → gastrula → cleavage
  - blastula → cleavage → gastrula
  - cleavage → gastrula → blastula
  - cleavage → blastula → gastrula
32. Which of the following does not describe axes of symmetry in animals?
- anterior-posterior
  - dorsal-ventral
  - upper-lower
  - lateral-median
33. Which of the following statements best summarizes the factors controlling symmetry?
- Axis formation is genetically determined.
  - Body symmetry is independent of genes.
  - Body symmetry is determined at the blastula stage.
  - Body symmetry is determined as the embryo grows in length.
34. The neural plate undergoes folding and movement of cells to form which structure?
- neural tube
  - epidermis
  - mesoderm
  - neural cord
35. What is necessary for normal human fertilization to occur?
- Many eggs must be released.
  - The uterus must be enlarged.
  - One sperm needs to penetrate one egg.
  - Secretion of pituitary FSH and LH must decrease.
36. Before pregnancy, progesterone is produced by the ovaries to thicken the endometrial lining and ensure pregnancy. During the third trimester of pregnancy, which organ produces progesterone?
- placenta
  - endometrial lining
  - chorion
  - corpus luteum

**37.** Which hormone is primarily responsible for the contractions during labor?

- a. oxytocin
- b. estrogen
- c.  $\beta$ -HCG
- d. progesterone

**38.** What happens before the baby and placenta are expelled?

- a. Thinning and dilation of the cervix take place.
- b. There is increased blood flow to the baby.
- c. Enlargement of the uterus takes place.
- d. Increased production of estrogen occurs.

**39.** Which type of short-term contraceptive method is generally more effective than others?

- a. barrier
- b. hormonal implants
- c. natural family planning
- d. withdrawal

**40.** Which of the following best indicates that a female is

ovulating?

- a. slight decrease in body temperature
- b. decrease in cervical volume
- c. more pliable cervical secretions
- d. change in breast size

**41.** Fertility is generally unaffected by \_\_\_\_\_.

- a. sexually transmitted diseases
- b. obstruction of reproductive tubes
- c. drug use
- d. genetic factors

**42.** What occurs in the procedure known as in vitro fertilization (IVF)?

- a. A sperm is injected into the egg externally.
- b. An egg is fertilized by the sperm internally in the oviduct.
- c. Eggs and sperm are combined externally and then implanted.
- d. Egg and sperm are combined externally and the resulting embryo is implanted.

## CRITICAL THINKING QUESTIONS

**43.** Due to global climate change and pollution, a lake experiences changes in temperature and pH. The lake has many species, including sexually reproducing frogs, water fleas that multiply by parthenogenesis, hydra that multiply by budding, and sponges that multiply by fragmentation. Which of these species will most likely survive the changing conditions of the lake?

- a. hydra
- b. sponges
- c. water fleas
- d. sexually-reproducing frogs

**44.** Why is sexual reproduction useful when only half the individuals reproduce and two cells must combine to form a new cell?

- a. It completes in a very short period of time.
- b. It results in the rapid production of many offspring.
- c. It increases genetic diversity, allowing organisms to survive in an unpredictable environment.
- d. It requires less energy and leads to genetic variation in the offspring.

**45.** Sex determination in humans and other mammals is dictated by the presence of sex chromosomes. Are there different factors that determine the sex of other types of animals?

- a. No, the sex of an individual is only determined by the presence of sex chromosomes.
- b. Yes, temperature also determines the sex of an individual.
- c. Yes, humidity and temperature determine the sex of an individual.
- d. Yes, pH and humidity determine the sex of an individual.

**46.** What are some advantages of internal compared with external fertilization?

- a. Internal fertilization leads to more genetic variations and increases the survival rates of offsprings.
- b. Internal fertilization increases the survival rates of offspring, and large numbers of offspring are produced.
- c. Internal fertilization increases the survival rates of offspring, and the chance of fertilization with a specific partner also increases.
- d. Internal fertilization increases the survival rates of offspring and decreases the chance of fertilization with a specific partner.

**47.** What are the mechanisms that protect and nurture the embryo in oviparous animals?

- a. The hard leathery exterior of bird eggs and the hard calcium covering of reptile eggs provides protection to the growing embryo. Nourishment is provided by yolk in the eggs.
- b. The hard leathery exterior of reptile eggs and the hard calcium covering of bird eggs provide protection to the growing embryo. Nourishment is provided by endosperm in the eggs.
- c. The hard leathery exterior of reptile eggs and the hard calcium covering of bird eggs provide protection to the growing embryo. Nourishment is provided by placenta in the eggs.
- d. The hard leathery exterior of reptile eggs and the hard calcium covering of bird eggs provide protection to the growing embryo. Nourishment is provided by yolk in the eggs.

**48.** Compare the specialization of reproductive structures found in different types of land animals.

- a. In birds, an opening called the cloaca is used to transfer sperm, whereas in mammals, the presence of the penis and vagina allows direct delivery. Complete reproductive systems are formed in insects, with eggs maturing in the testes and sperm maturing in the ovaries.
- b. In birds, an opening called the cloaca is used to transfer sperm, whereas in mammals, the presence of the penis and vagina allows direct delivery. Complete reproductive systems are formed in insects, with eggs maturing in the ovaries and sperm maturing in the testes.
- c. In birds, sperm are transferred via the spermatheca, whereas in mammals, the presence of the penis and vagina allows direct delivery. Complete reproductive systems are formed in insects, with eggs maturing in the ovaries and sperm maturing in the testes.
- d. In birds, an opening called the cloaca is used to transfer sperm, whereas in mammals, the presence of the penis and vagina allows direct delivery. Insects always use parthenogenesis.

**49.** Explain the fate of the newly released secondary oocyte after ovulation.

- a. If it fuses with a sperm, the resulting zygote enters the cervix for implantation. If it is not fertilized, it will return to the oviduct.
- b. If it fuses with a sperm, the resulting zygote enters the uterus for implantation. If it is not fertilized, it will return to oviduct.
- c. If it fuses with a sperm, the resulting zygote enters the uterus for implantation. If it is not fertilized, it will degrade and exit the body.
- d. If it fuses with a sperm, the resulting zygote enters the cervix for implantation. If it is not fertilized, it will degrade and exit the body.

**50.** Explain the similarities and differences in sexual response in males and females.

- a. Both males and females show specific arousal, but the sexual response differs in intensity and duration.
- b. Both males and females show specific arousal. In males, breathing rate and heart rate are increased. In females, there is a decrease in breathing rate and heart rate.
- c. Vasodilation occurs in both males and females, allowing blood to engorge erectile tissue in the nipples, clitoris, labia, vagina, and penis. In males, breathing rate and heart rate are increased. In females, there is a decrease in breathing rate and heart rate.
- d. Both males and females show an increase in heart rate, breathing rate, and blood pressure during phase one and phase two. However, sexual response differs in intensity and duration in males and females. Also, males show specific arousal, while females show non-specific arousal.

**51.** Compare and contrast spermatogenesis and oogenesis.

- a. Both are the form of gametogenesis that takes place through mitosis. Spermatogenesis is the process of formation of four sperm in the testes in males. The process of formation of one ovum in the ovaries in females is called oogenesis.
  - b. Both are the form of gametogenesis that takes place through meiosis. Spermatogenesis is the process of formation of four sperm in the testes in males. The process of formation of four ova in the ovaries in females is called oogenesis.
  - c. Both are the form of gametogenesis that takes place through meiosis. Spermatogenesis is the process of formation of four sperm in the testes in males. The process of formation of one ovum in the ovaries in females is called oogenesis.
  - d. Both are the form of gametogenesis that takes place through meiosis. Spermatogenesis is the process of formation of one sperm in the testes in males, while the process of formation of one ovum in the ovaries in females is called oogenesis.
- 52.** How does the hypothalamus regulate the secretion of reproductive hormones in males?
- a. The hypothalamus releases FSH and LH at puberty by secreting of GnRH. FSH stimulates the Leydig cells in the testes and LH stimulates the Sertoli cells to synthesize and secrete testosterone.
  - b. The hypothalamus releases FSH and LH at puberty by the secretion of GHRH. FSH stimulates the Sertoli cells in the testes and LH stimulates the Leydig cells to synthesize and secrete testosterone.
  - c. The hypothalamus stimulates the release of FSH and LH at puberty by secreting of GnRH. FSH stimulates the Sertoli cells in the testes and LH stimulates the Leydig cells to synthesize and secrete testosterone.
  - d. The hypothalamus releases TSH and LH at puberty by the secretion of GnRH. TSH stimulates the Sertoli cells in the testes and LH stimulates the Leydig cells to synthesize and secrete testosterone.
- 53.** What are the events that take place in a non-pregnant woman after ovulation?
- a. Because a fertilized egg is not implanted into the uterus in a non-pregnant woman, the corpus luteum degenerates, and the levels of estrogen and progesterone decrease. The endometrium begins to degenerate as the progesterone level drops, initiating the next menstrual cycle.
  - b. Because a fertilized egg is not implanted into the uterus in a non-pregnant woman, the corpus luteum degenerates, and the levels of estrogen and progesterone increase. The endometrium begins to degenerate as the estrogen level increases, initiating the next menstrual cycle.
  - c. Because a fertilized egg is not implanted into the uterus in a non-pregnant woman, the corpus luteum degenerates and the levels of estrogen and progesterone increase. The endometrium begins to degenerate as the progesterone level rises, initiating the next menstrual cycle.
  - d. Because a fertilized egg is not implanted into the uterus in a non-pregnant woman, the corpus luteum degenerates and the levels of estrogen and progesterone decrease. The myometrium begins to degenerate as the progesterone level drops, initiating the next menstrual cycle.

**54.** The side effects of menopause can be diminished by hormone replacement therapy (HRT). However, many doctors are hesitant to recommend it. What are the possible reasons for this?

- a. Its negative side effects, which include increased risk of colon cancer, osteoporosis, heart disease, macular degeneration, and possibly depression
- b. Its negative side effects, which include increased risk of stroke or heart attack, blood clots, breast cancer, ovarian cancer, endometrial cancer, gall bladder disease, and possibly depression.
- c. Its negative side effects, which include increased risk of stroke or heart attack, blood clots, breast cancer, colon cancer, endometrial cancer, gall bladder disease, and possibly dementia.
- d. Its negative side effects, which include increased risk of stroke or heart attack, blood clots, breast cancer, ovarian cancer, endometrial cancer, gall bladder disease and possibly dementia.

**55.** If multiple sperm were to combine with an egg, what would be the outcome?

- a. A cortical reaction would occur if multiple sperm combine with an egg, resulting in a genetically inviable embryo.
- b. The embryo would be genetically inviable and would die in a few days. The zygote might have multiple sets of chromosomes.
- c. The zygote might possess multiple sets of chromosomes, which will result in a neural tube defect in the developing fetus.
- d. The zygote would be viable, but the resulting embryo would be genetically inviable.

**56.** After the blastula is formed, where do the embryonic stem cells and germ layers originate?

- a. The inner cell mass contains embryonic stem cells, which arrange themselves into the three germ layers.
- b. The trophoblast in the blastula contains embryonic stem cells, which arrange themselves into three germ layers.
- c. The inner cell mass contains embryonic stem cells, whereas the germ cells originate from the trophoblast.
- d. The embryonic stem cells and germ layers originate from the blastocoel present inside the blastula.

**57.** What determines whether a zygote will undergo total or partial cleavage?

- a. Total cleavage takes place in eggs having a large amount of yolk, whereas partial cleavage occurs in eggs having very little or no yolk.
- b. Total cleavage occurs when eggs possess equal concentration of yolk at both poles, whereas partial cleavage occurs when the yolk is not equally distributed.
- c. Total cleavage takes place in eggs having little or no yolk, whereas partial cleavage occurs in eggs having a large amount of yolk.
- d. Total cleavage occurs when divisions of the blastomeres are separate, whereas partial cleavage occurs when blastomeres stay partially connected.

**58.** During organogenesis, the ectoderm forms the neural cells and the epidermal cells. How do the ectoderm cells determine which type of cells to form?

- a. Growth factors signal some of the ectodermal cells to form epidermal cells, and the remaining cells form the neural plate.
- b. The notochord cells of the mesoderm signal the ectodermal cells to form epidermal cells as well as the neural plate.
- c. Growth factors signal some of the ectodermal cells to form epidermal cells, and the remaining cells form neural crest cells.
- d. Proteins involved in the Wnt signaling pathway signal the ectodermal cells to form the epidermal cells and the neural plate.

**59.** What will be the outcome if the axis is not formed during the developmental stages?

- a. The animal will possess two notochords and may not have a dorsal-ventral or anterior-posterior side.
- b. The animal will lack an anterior-posterior or dorsal-ventral side and may not have complete differentiation of cell layers.
- c. The animal will lack an anterior-posterior or lateral-medial side and may not have complete differentiation of cell layers.
- d. The animal will have incorrect positioning of the dorsal-ventral and lateral-medial sides and differentiation of cell layers will be incomplete.

**60.** Explain what the mesoderm is and what it eventually differentiates into.

- a. The mesoderm, located on either side of the vertebrate neural tube, develops into various connective tissues. It is reorganized into groups of cells called somites, which develop into facial cartilage, ribs, and lungs.
- b. The mesoderm, located at the border of the neural plate and the non-neural ectoderm, develops into various connective tissues such as the ribs, lungs, segmental muscle, and the notochord, which forms the central axis of the animal body.
- c. The mesoderm, located on either side of the vertebrate neural tube, develops into various connective tissues. It is reorganized into groups of cells called somites, which develop into ribs, lungs, segmental muscle, and the notochord.
- d. The mesoderm, located at the border of the neural plate and the non-neural ectoderm, develops into various connective tissues such as the facial cartilage, ribs, and lungs.

**61.** Which best describes the three stages of labor?

- a. During stage one, the cervix thins. During stage two, the cervix is dilated to about 10 cm and the baby is expelled from the uterus. The last stage is the passage of the placenta after the baby has been born.
- b. During stage one, the cervix thins and is dilated to about 10 cm. During stage two, the baby is expelled from the uterus. The last stage is the passage of the placenta after the baby has been born.
- c. During stage one, the cervix thins. During stage two, the cervix is dilated to about 10 cm. During the last stage, the baby is expelled from the uterus, followed by the placenta.
- d. During stage one, the cervix thins and may or may not be dilated. During stage two, the baby is expelled from the uterus. The last stage is the passage of the placenta after the baby has been born.

## TEST PREP FOR AP® COURSES

**62.** If a plant species with a diploid number of 32 is crossed with another plant species with a diploid number of 24, what will be the diploid number of the resulting first generation of offspring? After the zygote multiplies to form a mass of cells, what is the chromosome number of each cell?

- a. 32, 28
- b. 24, 24
- c. 28, 28
- d. 28, 32

**63.** Compare and contrast sex determination in birds and mammals.

- a. In mammals, sex is determined by the presence of XX (homozygous) in males and XY (heterozygous) in females, while in birds, sex is determined by the presence of ZZ (homozygous) in females and ZW (heterozygous) in males.
- b. In mammals, sex is determined by the presence of XX (homozygous) in males and XY (heterozygous) in females, while in birds, sex is determined by the presence of ZW (heterozygous) in females and ZZ (homozygous) in males.
- c. In mammals, sex is determined by the presence of XX (homozygous) in females and XY (heterozygous) in males, while in birds, sex is determined by the presence of ZZ (homozygous) in females and ZW (heterozygous) in males.
- d. In mammals, sex is determined by the presence of XX (homozygous) in females and XY (heterozygous) in males, while in birds, sex is determined by the presence of ZW (heterozygous) in females and ZZ (homozygous) in males.

**64.** What is the advantage of sexual reproduction?

- a. Sexual reproduction allows animals to conserve resources and reproduce only during optimal conditions.
- b. Sexual reproduction results in offspring with diverse phenotypes, which may enhance survival of a population in a changing environment.
- c. Sexual reproduction guarantees that both parents will provide parental care.
- d. Sexual reproduction yields more numerous offspring more rapidly than is possible with asexual reproduction.

**65.** In sexual reproduction, two cells of a species combine to form another cell. Why is this useful?

- a. It produces new combination of genes, which enables offspring to survive during environmental changes.
- b. It results in the production of many offspring in a short period of time.
- c. It does not involve gamete formation and requires less energy.
- d. It allows immobile organisms to reproduce in the absence of a mate.

**66.** Spawning is often triggered by a signal such as water temperature or day length. What is an advantage of using this type of signal versus using individual courtship behaviors?

- a. It allows many individuals to spawn simultaneously without males and females having to choose individual mates.
- b. It is the only way that males and females can time gamete release simultaneously.
- c. These are the only types of signals that can be used.
- d. It increases the distance that gametes can travel.

**67.** Which of the following statements about hormone regulation of the female reproductive cycle is true?

- a. LH and FSH are produced in the ovaries, and estradiol and progesterone are produced in the pituitary.
- b. Estradiol and progesterone secreted from the corpus luteum cause the myometrium to thicken.
- c. Progesterone is produced by the corpus luteum.
- d. Secretion of GnRH by the hypothalamus is inhibited by high levels of estradiol, but stimulated by low levels of estradiol.

**68.** Which of the following statements about the menstrual cycle is TRUE?

- a. Estrogen levels rise during the luteal phase of the ovarian cycle and the secretory phase of the uterine cycle.
- b. Menstruation occurs much before LH and FSH levels peak.
- c. Menstruation occurs after progesterone levels rise.
- d. Progesterone levels rise before ovulation, while estrogen levels rise after.

**69.** What stimulates Leydig cells in the testes to produce testosterone?

- a. FSH
- b. LH
- c. inhibin
- d. estrogen

**70.** What is the nature of the oogonium and the secondary oocyte? Which process results in the formation of the secondary oocyte?

- a. A diploid oogonium forms a haploid oocyte by the process of mitosis.
- b. A haploid oogonium forms a diploid oocyte by the process of meiosis.
- c. A diploid oogonium forms a haploid oocyte by the process of meiosis.
- d. A haploid oogonium forms a haploid haploid oocyte by the process of meiosis.

**71.** Why are the diploid zygotes produced after fertilization of sperm cells produced by spermatogenesis not similar?

- a. Their chromosome numbers are not the same.
- b. The size of the sperm produced are different.
- c. Some sperm may have a tail, whereas others may not.
- d. Crossing over occurs during spermatogenesis.

**72.** The endocrine system incorporates feedback mechanisms that maintain homeostasis. Which of the following mechanisms demonstrates negative feedback by the reproductive system in mammals?

- a. Increasing levels of testosterone inhibit the production of GnRH, LH, and FSH by the hypothalamus and pituitary.
- b. LH and FSH stimulate the interstitial cells of Leydig to release testosterone.
- c. The growing follicle starts releasing estrogen in increasing amounts.
- d. The corpus luteum releases progesterone after ovulation.

**73.** Discuss the positive feedback mechanisms by LH and FSH during the follicular and ovulation phase of the

ovarian cycle.

- a. The stimulation of the anterior pituitary by GHRH secretes the hormones LH and FSH. The increasing amounts of these hormones stimulate several follicles in the ovary to start growing, but only one of these matures to release the egg.
- b. The stimulation of the anterior pituitary by GnRH secretes the hormones LH and TSH. The increasing amounts of these hormones stimulate several follicles in the ovary to start growing, but only one of these matures to release the egg.
- c. The stimulation of the anterior pituitary by GnRH triggers the secretion of the hormones LH and FSH. The increasing amounts of these hormones stimulate several follicles in the ovary to start growing, but only one of these matures to release the egg.
- d. The stimulation of the anterior pituitary by GHRH secretes the hormones LH and TSH. The increasing amounts of these hormones stimulate several follicles in the ovary to start growing, but only one of these matures to release the egg.

**74.** Describe the possible event that would occur if the corpus luteum did not produce increasing amounts of progesterone.

- a. The implanted zygote will not be able to derive sufficient nutrition from the endometrium.
- b. Even if fertilization is successful, the zygote may not be able to implant successfully. If it does manage to implant, it will not be able to derive sufficient nutrition from the myometrium.
- c. Even if fertilization is successful, the zygote may not be able to implant successfully. If it does manage to implant, it will not be able to derive sufficient nutrition from the endometrium.
- d. The contraction of the uterus during childbirth and lactation will not take place, causing problems and complications in the mother.

**75.** What does a female contraceptive pill that inhibits the release of GnRH from the hypothalamus do?

- a. reduce the secretion of FSH and LH from the anterior pituitary gland
- b. initiate ovulation
- c. increase the flow phase of the menstrual cycle
- d. increase the production of estrogen and progesterone by the ovaries

**76.** What do the rising levels of FSH and LH in the follicular phase cause?

- a. The follicles on the surface of the ovary start growing in preparation for ovulation.
- b. The endometrium starts to thicken.
- c. The corpus luteum starts secreting progesterone.
- d. One of the mature follicles bursts, releasing the egg.

**77.** A couple has been trying to conceive for some time and goes to an endocrinologist for advice. If the endocrinologist diagnoses an obstruction in the oviducts of the female, what type of treatment can she recommend?

- a. opting for in vivo fertilization or ligation of the fallopian tubes surgically so that the tubes are sealed
- b. opting for in vivo fertilization or removal of the obstruction surgically and then re-ligation of the ends of the fallopian tubes
- c. opting for in vitro fertilization or ligation of the fallopian tubes surgically so that the tubes are sealed
- d. opting for in vitro fertilization or removal of the obstruction surgically and then re-ligation of the ends of the fallopian tubes

**78.** How does a reproductive hormone that is secreted directly from the anterior pituitary stimulate the reproductive organs to produce hormones?

- a. by traveling through the blood to reach the target organs
- b. by binding with proteins to reach the reproductive organs
- c. by sending a chemical messenger to activate the reproductive organs
- d. by converting into an active form before targeting the reproductive organs

**79.** Explain the mechanisms by which hormones from the brain and ovaries interact, eventually leading to menstruation.

- a. After the release of the egg from the follicle, the corpus luteum is formed, which inhibits FSH and LH production, which then inhibits GnRH production, causing no other follicle to develop. When no fertilization takes place, the corpus luteum degenerates and the progesterone level declines, initiating the breakdown of the myometrium and the start of the menstrual cycle.
- b. After the release of the egg from the follicle, the corpus luteum is formed, which inhibits FSH and LH production, which then inhibits GnRH production, causing no other follicle to develop. When no fertilization takes place, the corpus luteum degenerates and the progesterone level declines, initiating the breakdown of the endometrium and the start of the menstrual cycle.
- c. After the release of the egg from the follicle, the corpus luteum is formed, which inhibits FSH and LH production, which then facilitates GnRH production, causing no other follicle to develop. When no fertilization takes place, the corpus luteum degenerates and the progesterone level declines, initiating the breakdown of the endometrium and the start of the menstrual cycle.
- d. After the release of the egg from the follicle, the corpus luteum is formed, which inhibits FSH and LH production, which then inhibits GnRH production, causing no other follicle to develop. When no fertilization takes place, the corpus luteum degenerates and the progesterone level rises, initiating the breakdown of the endometrium and the start of the menstrual cycle.

**80.** Multiple hormones work together to coordinate the female reproductive cycle. Which of these hormones is also responsible for the development of female secondary sexual characteristics, including breast development and hip widening?

- a. estrogen
- b. progesterone
- c. follicle stimulating hormone
- d. luteinizing hormone

## SCIENCE PRACTICE CHALLENGE QUESTIONS

**84.** Humans are bilateral and have biaxial symmetry. However, small variations in body symmetry occur. One foot may be slightly larger than another and we might never know. Because the eyes are so important in communication the condition called heterochromia iridium is very noticeable. Body plans are very noticeable aspects of the phenotype.

In guppy courtship the male displays himself to the

**81.** Which hormone is released by the anterior pituitary as a part of the positive feedback loop between it and the ovary?

- a. Progesterone
- b. GnRH
- c. LH
- d. Estradiol

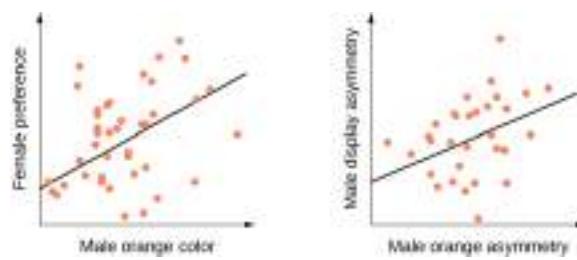

**82.** How does the feedback mechanism of hormones lead to muscular contractions during labor?

- a. A feedback relay occurs between the uterus, hypothalamus, and posterior pituitary to assure an adequate supply of oxytocin, which causes the contraction of smooth muscles of the uterus, leading to the birth of the baby.
- b. The posterior pituitary continuously produces oxytocin, which is sufficient for muscular contraction in the uterus, thereby causing the birth of the baby.
- c. A feedback relay occurs between the uterus, hypothalamus, and posterior pituitary to assure an adequate supply of prolactin, which causes the contraction of the smooth muscles of the uterus, leading to the birth of the baby.
- d. A feedback relay occurs between the uterus, hypothalamus, and posterior pituitary to assure an adequate supply of progesterone, which causes the contraction of the smooth muscles of the uterus, leading to the birth of the baby.

**83.** During childbirth, the hormone oxytocin causes contraction of the uterine wall muscles. As muscular contractions increase, more oxytocin is released from the pituitary, leading to more contractions. This is an example of which mechanism?

- a. end product inhibition
- b. negative feedback mechanism
- c. positive feedback mechanism
- d. feedback inhibition

female. Some males are more orange than others and some males have asymmetry with one side being more brightly colored orange than the other side. A pattern in the courtship display is shown in the graphs (Gross et al., *Proceedings of the Royal Society B: Biological Sciences*, 274, 2007).

**Figure 34.33**

A. **Analyze** the data to support the claim that the female guppy is responding to information, that the male guppy is aware of this response, and that this communication affects natural selection.

If there were no process that maintained variation in the gene controlling the orange coloration then perhaps all male guppies would symmetrically bright orange. Yet variation remains.

B. A guppy is a small fish and small fish are eaten by bigger fish. **Make and justify** a claim regarding the effect of allelic variation on the stability of the guppy population.

Phenotype is an expression of the genotype and within a population genotypic variation occurs. For a population to maintain stability in a changing environment genetic variation within the population provides selective

advantage at the population level.

C. **Make and justify** a claim regarding the effect of genetic variation in guppies on the stability of an ecosystem of which the guppy is a member.

The fluctuation of symmetry in body plan of an organism, such as the asymmetry of guppy coloration, is unusual. Large scale fluctuations where the fully developed organism is viable, such as the emergence of an appendage from the eye of the *Drosophila*, are very rare. The overall body plan is controlled in *Drosophila* by a cluster of genes called the Hox genes. In the fruit fly there is a single cluster and the arrangement of genes in the genome is a map of the anterior to posterior body plan. In all vertebrate multiple Hox clusters control the development of the body plan and they too show the sequential anterior to posterior arrangement in the genome.

D. During development the transcription factors expressed by the Hox genes initiate and terminate the expression of specialized cells and tissues. **Describe** the evidence for shared ancestry in this conserved strategy for communication between cells through regulation of transcription factors.

E. **Describe** one other example of conserved core shared by all domains or within one domain.

## Chapter Outline

- 35.1: The Scope of Ecology**
- 35.2: Biogeography**
- 35.3: Terrestrial Biomes**
- 35.4: Aquatic Biomes**
- 35.5: Climate and the Effects of Global Climate Change**

## Introduction

Why study ecology? Perhaps you are interested in learning about the natural world and how living things have adapted to the physical conditions of their environment. Or, perhaps you're a future physician seeking to understand the connection between human health and ecology.

Humans are a part of the ecological landscape, and human health is one important part of human interaction with our physical and living environment. Lyme disease, for instance, serves as one modern-day example of the connection between our health and the natural world (**Figure 35.1**). More formally known as Lyme borreliosis, Lyme disease is a bacterial infection that can be transmitted to humans when they are bitten by the deer tick (*Ixodes scapularis*), which is the primary vector for this disease. However, not all deer ticks carry the bacteria that will cause Lyme disease in humans, and *I. scapularis* can have other hosts besides deer. In fact, it turns out that the probability of infection depends on the type of host upon which the tick develops: a higher proportion of ticks that live on white-footed mice carry the bacterium than do ticks that live on deer. Knowledge about the environments and population densities in which the host species is abundant would help a physician or an epidemiologist better understand how Lyme disease is transmitted and how its incidence could be reduced.

For example, the mild winter in the northeast during 2010–2011 caused a boom in acorns, which in turn caused an increase in the white-footed mice population. However, the following winter was cooler, leading to fewer acorns, and the subsequent decrease in the mice population means that the ticks will be more likely to seek out humans for their blood meals. You can read more about the relationship between acorns, mice, and Lyme disease at the [Science Daily](#)

website (<http://openstaxcollege.org/l/32lyme>) and you can read more about Lyme disease from the **CDC website** (<http://openstaxcollege.org/l/32lymecdc>).

## 35.1 | The Scope of Ecology

In this section, you will explore the following questions:

- What is ecology, and what are the four levels of ecological research?
- What are examples of the ways in which ecology requires the integration of different scientific disciplines?
- What are examples of biotic and abiotic components of the environment?

### Connection for AP® Courses

**Ecology** is the study of the interactions among living organisms and with their environment. This includes relationships between organisms of the same species and also between different species. One core goal of ecology is to understand the distribution and abundance of organisms that inhabit the Earth. Ecology integrates multiple scientific disciplines in addition to biology, including molecular biology, physiology, evolution, biodiversity, geology, and climatology. Some ecological research also applies aspects of chemistry and physics, and it frequently uses mathematical models.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

|                                   |                                                                                                                                                                                                                                                 |
|-----------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Big Idea 4</b>                 | Biological systems interact, and these systems and their interactions possess complex properties.                                                                                                                                               |
| <b>Enduring Understanding 4.A</b> | Interactions within biological systems lead to complex properties.                                                                                                                                                                              |
| <b>Essential Knowledge</b>        | <b>4.A.6</b> Interactions among living organisms and with their environment results in the movement of matter and energy.                                                                                                                       |
| <b>Science Practice</b>           | <b>1.4</b> The student can use representations and models to analyze situations or solve problems qualitatively and quantitatively.                                                                                                             |
| <b>Learning Objective</b>         | <b>4.15</b> The student is able to use visual representations to analyze situations or solve problems qualitatively to illustrate how interactions among living systems and with their environment result in the movement of matter and energy. |

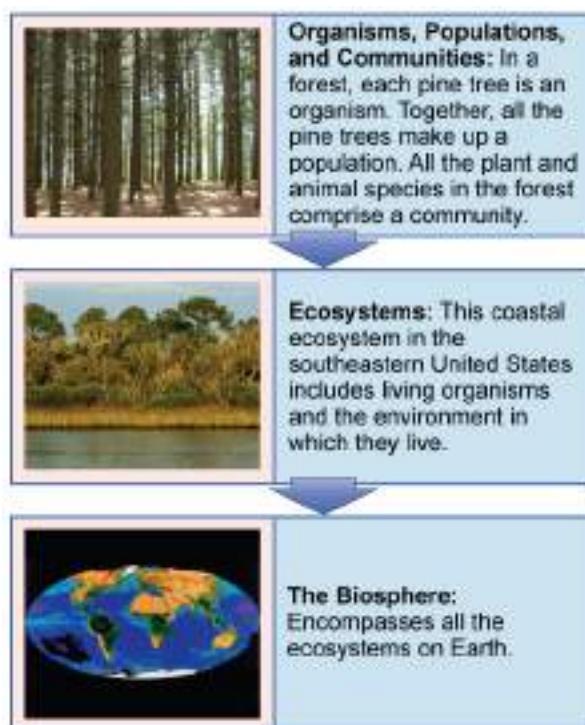

Climate change can alter where organisms live, which can sometimes directly affect human health. Watch the PBS video “**Feeling the Effects of Climate Change**” ([http://openstaxcollege.org/l/climate\\_health](http://openstaxcollege.org/l/climate_health)) in which researchers discover a pathogenic organism living far outside of its normal range.

The fungus *Cryptococcus gattii* has been known to cause a fatal illness. This fungus originally found in the tropics is now growing in parts of North America. What have scientists found out about this fungus?

- a. The fungus was inadvertently introduced in North America by travelers
- b. This fungus acquired pathogenic characteristics over time.
- c. The disease was caused by contact with infected people
- d. The fungus started growing more in colder climates as temperatures have risen due to global warming.

## Levels of Ecological Study

When a discipline such as biology is studied, it is often helpful to subdivide it into smaller, related areas. For instance, cell biologists interested in cell signaling need to understand the chemistry of the signal molecules (which are usually proteins) as well as the result of cell signaling. Ecologists interested in the factors that influence the survival of an endangered species might use mathematical models to predict how current conservation efforts affect endangered organisms. To produce a sound set of management options, a conservation biologist needs to collect accurate data, including current population size, factors affecting reproduction (like physiology and behavior), habitat requirements (such as plants and soils), and potential human influences on the endangered population and its habitat (which might be derived through studies in sociology and urban ecology). Within the discipline of ecology, researchers work at four specific levels, sometimes discretely and sometimes with overlap: organism, population, community, and ecosystem (**Figure 35.2**).

**Figure 35.2** Ecologists study within several biological levels of organization. (credit “organisms”: modification of work by "Crystl"/Flickr; credit “ecosystems”: modification of work by Tom Carlisle, US Fish and Wildlife Service Headquarters; credit “biosphere”: NASA)

## Organismal Ecology

Researchers studying ecology at the organismal level are interested in the adaptations that enable individuals to live in specific habitats. These adaptations can be morphological, physiological, and behavioral. For instance, the Karner blue butterfly (*Lycaeides melissa samuelis*) (Figure 35.3) is considered a specialist because the females preferentially oviposit (that is, lay eggs) on wild lupine. This preferential adaptation means that the Karner blue butterfly is highly dependent on the presence of wild lupine plants for its continued survival.

**Figure 35.3** The Karner blue butterfly (*Lycaeides melissa samuelis*) is a rare butterfly that lives only in open areas with few trees or shrubs, such as pine barrens and oak savannas. It can only lay its eggs on lupine plants. (credit: modification of work by J & K Hollingsworth, USFWS)

After hatching, the larval caterpillars emerge and spend four to six weeks feeding solely on wild lupine (Figure 35.4). The caterpillars pupate (undergo metamorphosis) and emerge as butterflies after about four weeks. The adult butterflies feed on the nectar of flowers of wild lupine and other plant species. A researcher interested in studying Karner blue butterflies at the organismal level might, in addition to asking questions about egg laying, ask questions about the butterflies’ preferred temperature (a physiological question) or the behavior of the caterpillars when they are at different larval stages (a behavioral question).

**Figure 35.4** The wild lupine (*Lupinus perennis*) is the host plant for the Karner blue butterfly.

## Population Ecology

A population is a group of interbreeding organisms that are members of the same species living in the same area at the same time. (Organisms that are all members of the same species are called **conspecifics**.) A population is identified, in part, by where it lives, and its area of population may have natural or artificial boundaries: natural boundaries might be rivers, mountains, or deserts, while examples of artificial boundaries include mowed grass, manmade structures, or roads. The study of population ecology focuses on the number of individuals in an area and how and why population size changes over time. Population ecologists are particularly interested in counting the Karner blue butterfly, for example, because it is classified as federally endangered. However, the distribution and density of this species is highly influenced by the distribution and abundance of wild lupine. Researchers might ask questions about the factors leading to the decline of wild lupine and how these affect Karner blue butterflies. For example, ecologists know that wild lupine thrives in open areas where trees and shrubs are largely absent. In natural settings, intermittent wildfires regularly remove trees and shrubs, helping to maintain the open areas that wild lupine requires. Mathematical models can be used to understand how wildfire suppression by humans has led to the decline of this important plant for the Karner blue butterfly.

## Community Ecology

A biological community consists of the different species within an area, typically a three-dimensional space, and the interactions within and among these species. Community ecologists are interested in the processes driving these interactions and their consequences. Questions about conspecific interactions often focus on competition among members of the same species for a limited resource. Ecologists also study interactions among various species; members of different species are called **heterospecifics**. Examples of heterospecific interactions include predation, parasitism, herbivory, competition, and pollination. These interactions can have regulating effects on population sizes and can impact ecological and evolutionary processes affecting diversity.

For example, Karner blue butterfly larvae form mutualistic relationships with ants. Mutualism is a form of a long-term relationship that has coevolved between two species and from which each species benefits. For mutualism to exist between individual organisms, each species must receive some benefit from the other as a consequence of the relationship. Researchers have shown that there is an increase in the probability of survival when Karner blue butterfly larvae (caterpillars) are tended by ants. This might be because the larvae spend less time in each life stage when tended by ants, which provides an advantage for the larvae. Meanwhile, the Karner blue butterfly larvae secrete a carbohydrate-rich substance that is an important energy source for the ants. Both the Karner blue larvae and the ants benefit from their interaction.

## Ecosystem Ecology

Ecosystem ecology is an extension of organismal, population, and community ecology. The ecosystem is composed of all

the **biotic** components (living things) in an area along with the **abiotic** components (non-living things) of that area. Some of the abiotic components include air, water, and soil. Ecosystem biologists ask questions about how nutrients and energy are stored and how they move among organisms and the surrounding atmosphere, soil, and water.

The Karner blue butterflies and the wild lupine live in an oak-pine barren habitat. This habitat is characterized by natural disturbance and nutrient-poor soils that are low in nitrogen. The availability of nutrients is an important factor in the distribution of the plants that live in this habitat. Researchers interested in ecosystem ecology could ask questions about the importance of limited resources and the movement of resources, such as nutrients, though the biotic and abiotic portions of the ecosystem.

## career CONNECTION

### Ecologist

A career in ecology contributes to many facets of human society. Understanding ecological issues can help society meet the basic human needs of food, shelter, and health care. Ecologists can conduct their research in the laboratory and outside in natural environments (Figure 35.5). These natural environments can be as close to home as the stream running through your campus or as far away as the hydrothermal vents at the bottom of the Pacific Ocean. Ecologists manage natural resources such as white-tailed deer populations (*Odocoileus virginianus*) for hunting or aspen (*Populus spp.*) timber stands for paper production. Ecologists also work as educators who teach children and adults at various institutions including universities, high schools, museums, and nature centers. Ecologists may also work in advisory positions assisting local, state, and federal policymakers to develop laws that are ecologically sound, or they may develop those policies and legislation themselves. To become an ecologist requires an undergraduate degree, usually in a natural science. The undergraduate degree is often followed by specialized training or an advanced degree, depending on the area of ecology selected. Ecologists should also have a broad background in the physical sciences, as well as a sound foundation in mathematics and statistics.

**Figure 35.5** This landscape ecologist is releasing a black-footed ferret into its native habitat as part of a study. (credit: USFWS Mountain Prairie Region, NPS)

Visit this site ([http://openstaxcollege.org/l/ecologist\\_role](http://openstaxcollege.org/l/ecologist_role)) to see Stephen Wing, a marine ecologist from the University of Otago, discuss the role of an ecologist and the types of issues ecologists explore.

A marine ecologist studies interactions in the ocean. Which of the following subjects would a marine ecologist include in his studies?

- a. chemistry
- b. philosophy
- c. political science
- d. epidemiology

## 35.2 | Biogeography

In this section, you will explore the following questions:

- What is biogeography?
- What are examples of abiotic factors that affect the global distribution of plant and animal species?
- What are examples of how abiotic factors can impact aquatic and terrestrial environments?
- What are the effects of abiotic factors on net primary productivity?

### Connection for AP® Courses

Many forces influence the communities of living organisms present in different parts of the biosphere (all of the parts of Earth inhabited by life). The biosphere extends into the atmosphere (several kilometers above Earth) and into the depths of the oceans. Despite its apparent vastness to an individual human, the biosphere occupies only a minute space when compared to the known universe. Many abiotic forces influence where life can exist and the types of organisms found in different parts of the biosphere. The abiotic factors influence the distribution of **biomes**: large areas of land with similar climate, flora, and fauna.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Learning Objective</b>  | <b>2.24</b> The student is able to analyze data to identify possible patterns and relationships between a biotic or abiotic factor and a biological system.                                                                            |

## Biogeography

**Biogeography** is the study of the geographic distribution of living things and the abiotic factors that affect their distribution. Abiotic factors such as temperature and rainfall vary based mainly on latitude and elevation. As these abiotic factors change, the composition of plant and animal communities also changes. For example, if you were to begin a journey at the equator and walk north, you would notice gradual changes in plant communities. At the beginning of your journey, you would see tropical wet forests with broad-leaved evergreen trees, which are characteristic of plant communities found near the equator. As you continued to travel north, you would see these broad-leaved evergreen plants eventually give rise to seasonally dry forests with scattered trees. You would also begin to notice changes in temperature and moisture. At about 30 degrees north, these forests would give way to deserts, which are characterized by low precipitation.

Moving farther north, you would see that deserts are replaced by grasslands or prairies. Eventually, grasslands are replaced by deciduous temperate forests. These deciduous forests give way to the boreal forests found in the subarctic, the area south of the Arctic Circle. Finally, you would reach the Arctic tundra, which is found at the most northern latitudes. This trek north reveals gradual changes in both climate and the types of organisms that have adapted to environmental factors associated with ecosystems found at different latitudes. However, different ecosystems exist at the same latitude due in part to abiotic factors such as jet streams, the Gulf Stream, and ocean currents. If you were to hike up a mountain, the changes you would see in the vegetation would parallel those as you move to higher latitudes.

Ecologists who study biogeography examine patterns of species distribution. No species exists everywhere; for example, the Venus flytrap is endemic to a small area in North and South Carolina. An **endemic** species is one which is naturally found only in a specific geographic area that is usually restricted in size. Other species are generalists: species which live in a wide variety of geographic areas; the raccoon, for example, is native to most of North and Central America.

Species distribution patterns are based on biotic and abiotic factors and their influences during the very long periods of time required for species evolution; therefore, early studies of biogeography were closely linked to the emergence of evolutionary thinking in the eighteenth century. Some of the most distinctive assemblages of plants and animals occur in regions that have been physically separated for millions of years by geographic barriers. Biologists estimate that Australia, for example, has between 600,000 and 700,000 species of plants and animals. Approximately 3/4 of living plant and mammal species are endemic species found solely in Australia (**Figure 35.6ab**).

(a)

(b)

**Figure 35.6** Australia is home to many endemic species. The (a) wallaby (*Wallabia bicolor*), a medium-sized member of the kangaroo family, is a pouched mammal, or marsupial. The (b) echidna (*Tachyglossus aculeatus*) is an egg-laying mammal. (credit a: modification of work by Derrick Coetzee; credit b: modification of work by Allan Whittome)

Sometimes ecologists discover unique patterns of species distribution by determining where species are *not* found. Hawaii, for example, has no native land species of reptiles or amphibians, and has only one native terrestrial mammal, the hoary bat. Most of New Guinea, as another example, lacks placental mammals.

Check out this [video](http://openstaxcollege.org/l/platypus) (<http://openstaxcollege.org/l/platypus>) to observe a platypus swimming in its natural habitat in New South Wales, Australia.

Marsupials such as such as wallabies, platypuses, and kangaroos are found exclusively in Australia. Species found in a limited area are most specifically called \_\_\_\_\_.

- a. endemic species
- b. generalist species
- c. native species
- d. common species

Plants can be endemic or generalists: endemic plants are found only on specific regions of the Earth, while generalists are found on many regions. Isolated land masses—such as Australia, Hawaii, and Madagascar—often have large numbers of endemic plant species. Some of these plants are endangered due to human activity. The forest gardenia (*Gardenia brighamii*), for instance, is endemic to Hawaii; only an estimated 15–20 trees are thought to exist ([Figure 35.7](#)).

## science practices CONNECTION for AP<sup>®</sup> Courses

### Think About It

Many endemic species are found in areas that are geographically isolated. What is a possible scientific explanation for this observation? Justify your answer.

### Lab Investigation

Use *The College Board Advanced Placement Program: Measuring Primary Productivity—Grass Plants: Student Lab Template*, found [here](http://openstaxcollege.org/l/32grass) (<http://openstaxcollege.org/l/32grass>) to explore the concept of primary productivity versus gross productivity. You will calculate primary productivity, be introduced to the benefits of measuring dry mass versus wet mass, and make predictions about the changes in net primary productivity based on the variables you decide to focus on.

To learn more about calculating net primary productivity, watch [this video](https://openstaxcollege.org/l/32nppcalc) (<https://openstaxcollege.org/l/32nppcalc>) .

**Figure 35.7** Listed as federally endangered, the forest gardenia is a small tree with distinctive flowers. It is found only in five of the Hawaiian Islands in small populations consisting of a few individual specimens. (credit: Forest & Kim Starr)

### Energy Sources

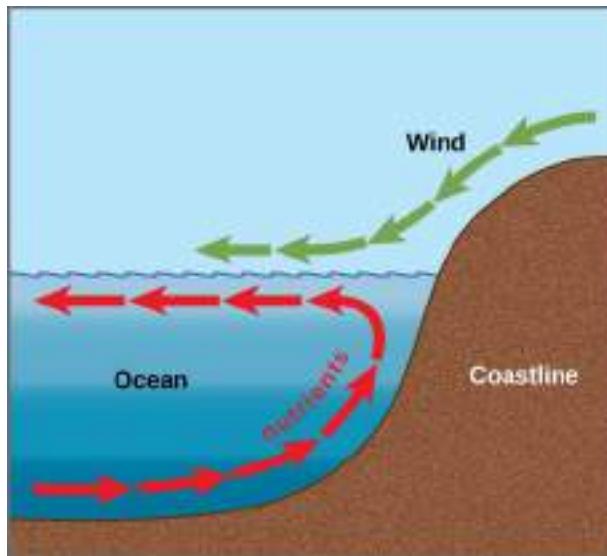

Energy from the sun is captured by green plants, algae, cyanobacteria, and photosynthetic protists. These organisms convert solar energy into the chemical energy needed by all living things. Light availability can be an important force directly affecting the evolution of adaptations in photosynthesizers. For instance, plants in the understory of a temperate forest are shaded when the trees above them in the canopy completely leaf out in the late spring. Not surprisingly, understory plants have adaptations to successfully capture available light. One such adaptation is the rapid growth of spring ephemeral plants such as the spring beauty (Figure 35.8). These spring flowers achieve much of their growth and finish their life cycle (reproduce) early in the season before the trees in the canopy develop leaves.

**Figure 35.8** The spring beauty is an ephemeral spring plant that flowers early in the spring to avoid competing with larger forest trees for sunlight. (credit: John Beetham)

In aquatic ecosystems, the availability of light may be limited because sunlight is absorbed by water, plants, suspended particles, and resident microorganisms. Toward the bottom of a lake, pond, or ocean, there is a zone that light cannot reach. Photosynthesis cannot take place there and, as a result, a number of adaptations have evolved that enable living things to survive without light. For instance, aquatic plants have photosynthetic tissue near the surface of the water; for example, think of the broad, floating leaves of a water lily—water lilies cannot survive without light. In environments such as hydrothermal vents, some bacteria extract energy from inorganic chemicals because there is no light for photosynthesis.

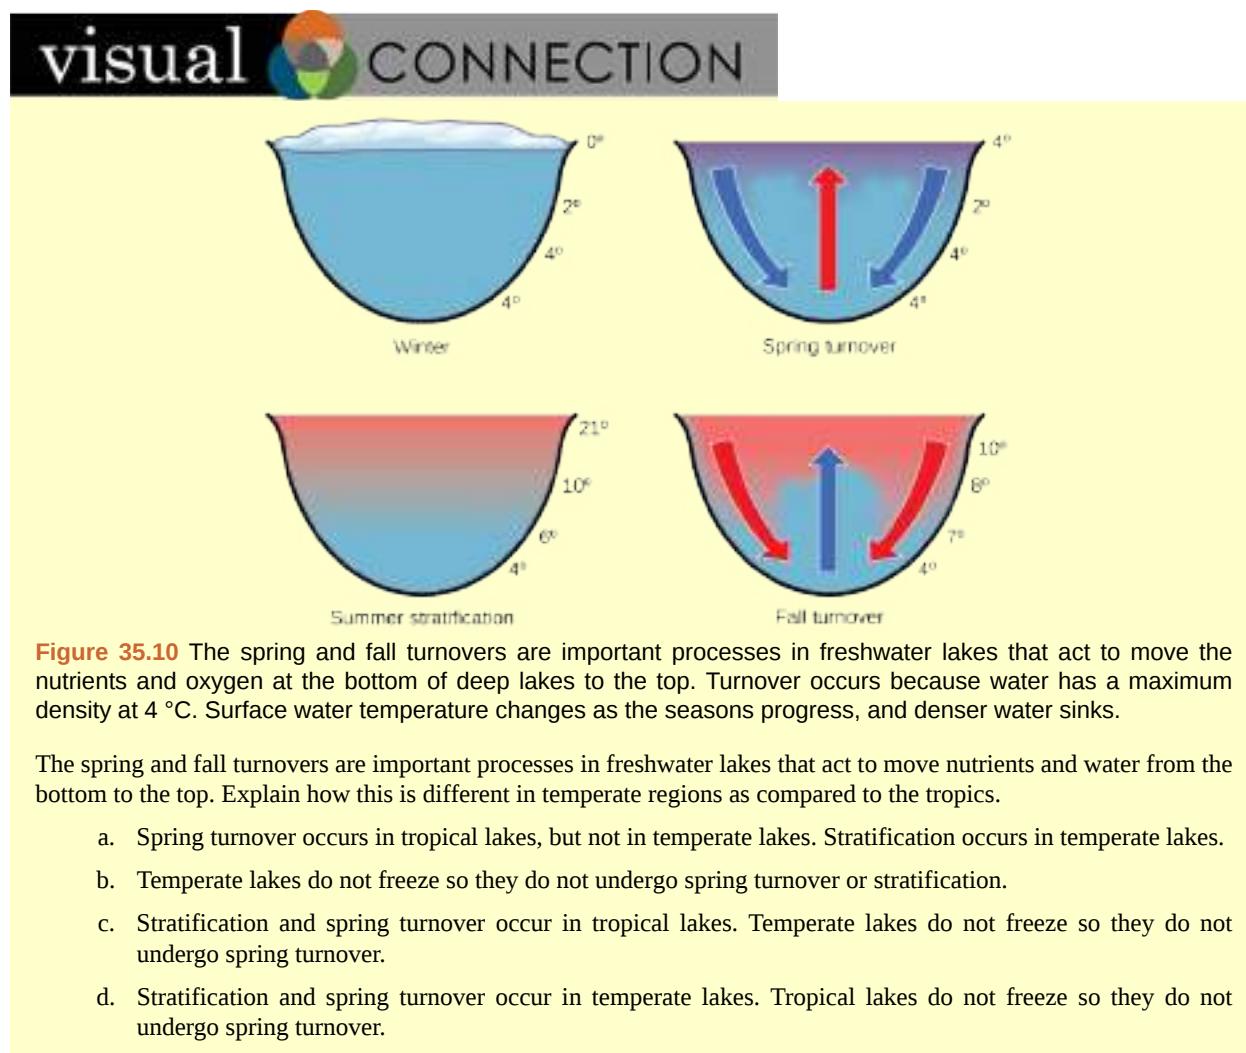

The availability of nutrients in aquatic systems is also an important aspect of energy or photosynthesis. Many organisms sink to the bottom of the ocean when they die in the open water; when this occurs, the energy found in that living organism is sequestered for some time unless ocean upwelling occurs. **Ocean upwelling** is the rising of deep ocean waters that occurs when prevailing winds blow along surface waters near a coastline (**Figure 35.9**). As the wind pushes ocean waters offshore, water from the bottom of the ocean moves up to replace this water. As a result, the nutrients once contained in dead organisms become available for reuse by other living organisms.

**Figure 35.9** Ocean upwelling is an important process that recycles nutrients and energy in the ocean. As wind (green arrows) pushes offshore, it causes water from the ocean bottom (red arrows) to move to the surface, bringing up nutrients from the ocean depths.

In freshwater systems, the recycling of nutrients occurs in response to air temperature changes. The nutrients at the bottom of lakes are recycled twice each year: in the spring and fall turnover. The **spring and fall turnover** is a seasonal process that recycles nutrients and oxygen from the bottom of a freshwater ecosystem to the top of a body of water (**Figure 35.10**). These turnovers are caused by the formation of a **thermocline**: a layer of water with a temperature that is significantly different

from that of the surrounding layers. In wintertime, the surface of lakes found in many northern regions is frozen. However, the water under the ice is slightly warmer, and the water at the bottom of the lake is warmer yet at 4 °C to 5 °C (39.2 °F to 41 °F). Water is densest at 4 °C; therefore, the deepest water is also the densest. The deepest water is oxygen poor because the decomposition of organic material at the bottom of the lake uses up available oxygen that cannot be replaced by means of oxygen diffusion into the water due to the surface ice layer.

**Figure 35.10** The spring and fall turnovers are important processes in freshwater lakes that act to move the nutrients and oxygen at the bottom of deep lakes to the top. Turnover occurs because water has a maximum density at 4 °C. Surface water temperature changes as the seasons progress, and denser water sinks.

The spring and fall turnovers are important processes in freshwater lakes that act to move nutrients and water from the bottom to the top. Explain how this is different in temperate regions as compared to the tropics.

- Spring turnover occurs in tropical lakes, but not in temperate lakes. Stratification occurs in temperate lakes.
- Temperate lakes do not freeze so they do not undergo spring turnover or stratification.
- Stratification and spring turnover occur in tropical lakes. Temperate lakes do not freeze so they do not undergo spring turnover.
- Stratification and spring turnover occur in temperate lakes. Tropical lakes do not freeze so they do not undergo spring turnover.

In springtime, air temperatures increase and surface ice melts. When the temperature of the surface water begins to reach 4 °C, the water becomes heavier and sinks to the bottom. The water at the bottom of the lake is then displaced by the heavier surface water and, thus, rises to the top. As that water rises to the top, the sediments and nutrients from the lake bottom are brought along with it. During the summer months, the lake water stratifies, or forms layers, with the warmest water at the lake surface.

As air temperatures drop in the fall, the temperature of the lake water cools to 4 °C; therefore, this causes fall turnover as the heavy cold water sinks and displaces the water at the bottom. The oxygen-rich water at the surface of the lake then moves to the bottom of the lake, while the nutrients at the bottom of the lake rise to the surface (**Figure 35.10**). During the winter, the oxygen at the bottom of the lake is used by decomposers and other organisms requiring oxygen, such as fish.

#### Temperature

Temperature affects the physiology of living things as well as the density and state of water. Temperature exerts an important influence on living things because few living things can survive at temperatures below 0 °C (32 °F) due to metabolic constraints. It is also rare for living things to survive at temperatures exceeding 45 °C (113 °F); this is a reflection of evolutionary response to typical temperatures. Enzymes are most efficient within a narrow and specific range of temperatures; enzyme degradation can occur at higher temperatures. Therefore, organisms either must maintain an

internal temperature or they must inhabit an environment that will keep the body within a temperature range that supports metabolism. Some animals have adapted to enable their bodies to survive significant temperature fluctuations, such as seen in hibernation or reptilian torpor. Similarly, some bacteria are adapted to surviving in extremely hot temperatures such as geysers. Such bacteria are examples of extremophiles: organisms that thrive in extreme environments.

Temperature can limit the distribution of living things. Animals faced with temperature fluctuations may respond with adaptations, such as migration, in order to survive. Migration, the movement from one place to another, is an adaptation found in many animals, including many that inhabit seasonally cold climates. Migration solves problems related to temperature, locating food, and finding a mate. In migration, for instance, the Arctic Tern (*Sterna paradisaea*) makes a 40,000 km (24,000 mi) round trip flight each year between its feeding grounds in the southern hemisphere and its breeding grounds in the Arctic Ocean. Monarch butterflies (*Danaus plexippus*) live in the eastern United States in the warmer months and migrate to Mexico and the southern United States in the wintertime. Some species of mammals also make migratory forays. Reindeer (*Rangifer tarandus*) travel about 5,000 km (3,100 mi) each year to find food. Amphibians and reptiles are more limited in their distribution because they lack migratory ability. Not all animals that can migrate do so: migration carries risk and comes at a high energy cost.

Some animals hibernate or estivate to survive hostile temperatures. Hibernation enables animals to survive cold conditions, and estivation allows animals to survive the hostile conditions of a hot, dry climate. Animals that hibernate or estivate enter a state known as torpor: a condition in which their metabolic rate is significantly lowered. This enables the animal to wait until its environment better supports its survival. Some amphibians, such as the wood frog (*Rana sylvatica*), have an antifreeze-like chemical in their cells, which retains the cells' integrity and prevents them from bursting.

### Water

Water is required by all living things because it is critical for cellular processes. Since terrestrial organisms lose water to the environment by simple diffusion, they have evolved many adaptations to retain water.

- Plants have a number of interesting features on their leaves, such as leaf hairs and a waxy cuticle, that serve to decrease the rate of water loss via transpiration.
- Freshwater organisms are surrounded by water and are constantly in danger of having water rush into their cells because of osmosis. Many adaptations of organisms living in freshwater environments have evolved to ensure that solute concentrations in their bodies remain within appropriate levels. One such adaptation is the excretion of dilute urine.
- Marine organisms are surrounded by water with a higher solute concentration than the organism and, thus, are in danger of losing water to the environment because of osmosis. These organisms have morphological and physiological adaptations to retain water and release solutes into the environment. For example, Marine iguanas (*Amblyrhynchus cristatus*), sneeze out water vapor that is high in salt in order to maintain solute concentrations within an acceptable range while swimming in the ocean and eating marine plants.

### Inorganic Nutrients and Soil

Inorganic nutrients, such as nitrogen and phosphorus, are important in the distribution and the abundance of living things. Plants obtain these inorganic nutrients from the soil when water moves into the plant through the roots. Therefore, soil structure (particle size of soil components), soil pH, and soil nutrient content play an important role in the distribution of plants. Animals obtain inorganic nutrients from the food they consume. Therefore, animal distributions are related to the distribution of what they eat. In some cases, animals will follow their food resource as it moves through the environment.

### Other Aquatic Factors

Some abiotic factors, such as oxygen, are important in aquatic ecosystems as well as terrestrial environments. Terrestrial animals obtain oxygen from the air they breathe. Oxygen availability can be an issue for organisms living at very high elevations, however, where there are fewer molecules of oxygen in the air. In aquatic systems, the concentration of dissolved oxygen is related to water temperature and the speed at which the water moves. Cold water has more dissolved oxygen than warmer water. In addition, salinity, current, and tide can be important abiotic factors in aquatic ecosystems.

### Other Terrestrial Factors

Wind can be an important abiotic factor because it influences the rate of evaporation and transpiration. The physical force of wind is also important because it can move soil, water, or other abiotic factors, as well as an ecosystem's organisms.

Fire is another terrestrial factor that can be an important agent of disturbance in terrestrial ecosystems. Some organisms are adapted to fire and, thus, require the high heat associated with fire to complete a part of their life cycle. For example, the jack pine—a coniferous tree—requires heat from fire for its seed cones to open (Figure 35.11). Through the burning of pine needles, fire adds nitrogen to the soil and limits competition by destroying undergrowth.

**Figure 35.11** The mature cones of the jack pine (*Pinus banksiana*) open only when exposed to high temperatures, such as during a forest fire. A fire is likely to kill most vegetation, so a seedling that germinates after a fire is more likely to receive ample sunlight than one that germinates under normal conditions. (credit: USDA)

## Abiotic Factors Influencing Plant Growth

Temperature and moisture are important influences on plant production (primary productivity) and the amount of organic matter available as food (net primary productivity). **Net primary productivity** is an estimation of all of the organic matter available as food; it is calculated as the total amount of carbon fixed per year minus the amount that is oxidized during cellular respiration. In terrestrial environments, net primary productivity is estimated by measuring the **aboveground biomass** per unit area, which is the total mass of living plants, excluding roots. This means that a large percentage of plant biomass which exists underground is not included in this measurement. Net primary productivity is an important variable when considering differences in biomes. Very productive biomes have a high level of aboveground biomass.

Annual biomass production is directly related to the abiotic components of the environment. Environments with the greatest amount of biomass have conditions in which photosynthesis, plant growth, and the resulting net primary productivity are optimized. The climate of these areas is warm and wet. Photosynthesis can proceed at a high rate, enzymes can work most efficiently, and stomata can remain open without the risk of excessive transpiration; together, these factors lead to the maximal amount of carbon dioxide (CO<sub>2</sub>) moving into the plant, resulting in high biomass production. The aboveground biomass produces several important resources for other living things, including habitat and food. Conversely, dry and cold environments have lower photosynthetic rates and therefore less biomass. The animal communities living there will also be affected by the decrease in available food.

## 35.3 | Terrestrial Biomes

In this section, you will explore the following questions:

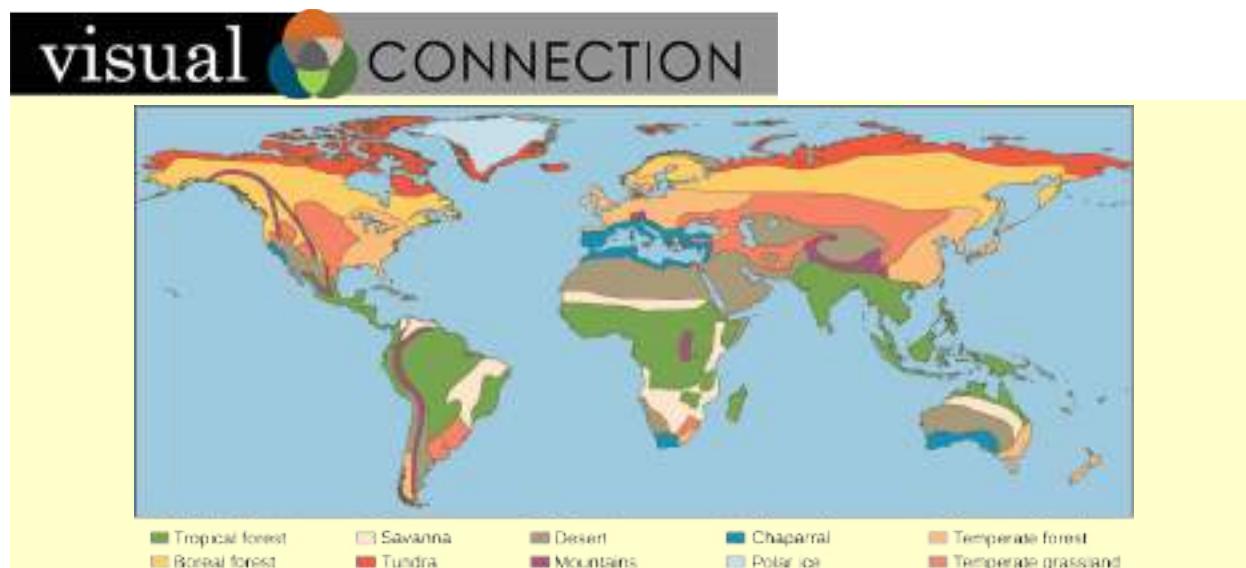

- What are the two major abiotic factors that determine terrestrial biomes?
- What are distinguishing characteristics of each of the major terrestrial biomes?

### Connection for AP® Courses

Much of the information in this section is outside the scope of AP®. You do not need to memorize a list of Earth's major terrestrial biomes and their descriptive features. However, we learned previously that organisms interact with each other and with their environments to move matter and energy. Biomes are ripe with examples of these interactions. A biome refers to a major type of terrestrial (or aquatic) community distributed according to climate, which determines the predominant vegetation. In turn, the vegetation influences what types of animals can inhabit the area. Comparing the annual totals of precipitation and fluctuations in precipitation from one biome to another provides clues as to the importance of abiotic factors in the distribution of biomes. The same type of biome can occur in different areas of the world (Figure 35.12).

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

**Figure 35.12** Each of the world's major biomes is distinguished by characteristic temperatures and amounts of precipitation. Polar ice and mountains are also shown.

Which of the following statements about biomes is false?

- Chapparal is dominated by shrubs.
- Grasses dominate savannas and temperate grasslands.
- Boreal forests are dominated by deciduous trees.
- Lichens are common in the arctic tundra.

## Tropical Wet Forest

Tropical wet forests are also referred to as tropical rainforests. This biome is found in equatorial regions ([Figure 35.12](#)). The vegetation is characterized by plants with broad leaves that fall off throughout the year. Unlike the trees of deciduous forests, the trees in this biome do not have a seasonal loss of leaves associated with variations in temperature and sunlight; these forests are “evergreen” year-round.

The temperature and sunlight profiles of tropical wet forests are very stable in comparison to that of other terrestrial biomes, with the temperatures ranging from 20 °C to 34 °C (68 °F to 93 °F). When one compares the annual temperature variation of tropical wet forests with that of other forest biomes, the lack of seasonal temperature variation in the tropical wet forest becomes apparent. This lack of seasonality leads to year-round plant growth, rather than the seasonal (spring, summer, and fall) growth seen in other biomes. In contrast to other ecosystems, tropical ecosystems do not have long days and short days during the yearly cycle. Instead, a constant daily amount of sunlight (11–12 hrs per day) provides more solar radiation, thereby, a longer period of time for plant growth.

The annual rainfall in tropical wet forests ranges from 125 to 660 cm (50–200 in) with some monthly variation. While sunlight and temperature remain fairly consistent, annual rainfall is highly variable. Tropical wet forests have wet months in which there can be more than 30 cm (11–12 in) of precipitation, as well as dry months in which there are fewer than 10 cm (3.5 in) of rainfall. However, the driest month of a tropical wet forest still exceeds the *annual* rainfall of some other biomes, such as deserts.

Tropical wet forests have high net primary productivity because the annual temperatures and precipitation values in these areas are ideal for plant growth. Therefore, the extensive biomass present in the tropical wet forest leads to plant communities with very high species diversities ([Figure 35.13](#)). Tropical wet forests have more species of trees than any other biome; on average between 100 and 300 species of trees are present in a single hectare (2.5 acres) of South America. One way to visualize this is to compare the distinctive horizontal layers within the tropical wet forest biome. On the forest floor is a sparse layer of plants and decaying plant matter. Above that is an understory of short shrubby foliage. A layer of trees rises above this understory and is topped by a closed upper **canopy**—the uppermost overhead layer of branches and leaves. Some additional trees emerge through this closed upper canopy. These layers provide diverse and complex habitats for the variety of plants, fungi, animals, and other organisms within the tropical wet forests. For instance, epiphytes are plants that grow on other plants, which typically are not harmed. Epiphytes are found throughout tropical wet forest biomes. Many species of animals use the variety of plants and the complex structure of the tropical wet forests for food and shelter. Some organisms live several meters above ground and have adapted to this arboreal lifestyle.

**Figure 35.13** Tropical wet forests, such as these forests of Madre de Dios, Peru, near the Amazon River, have high species diversity. (credit: Roosevelt Garcia)

## Savannas

Savannas are grasslands with scattered trees, and they are located in Africa, South America, and northern Australia ([Figure 35.12](#)). Savannas are hot, tropical areas with temperatures averaging from 24 °C to 29 °C (75 °F to 84 °F) and an annual rainfall of 10–40 cm (3.9–15.7 in). Savannas have an extensive dry season; for this reason, forest trees do not grow as well as they do in the tropical wet forest (or other forest biomes). As a result, within the grasses and forbs (herbaceous flowering plants) that dominate the savanna, there are relatively few trees ([Figure 35.14](#)). Since fire is an important source of disturbance in this biome, plants have evolved well-developed root systems that allow them to quickly re-sprout after a

fire.

**Figure 35.14** Savannas, like this one in Taita Hills Wildlife Sanctuary in Kenya, are dominated by grasses. (credit: Christopher T. Cooper)

## Subtropical Deserts

Subtropical deserts exist between 15 ° and 30 ° north and south latitude and are centered on the Tropics of Cancer and Capricorn ([Figure 35.12](#)). This biome is very dry; in some years, evaporation exceeds precipitation. Subtropical hot deserts can have daytime soil surface temperatures above 60 °C (140 °F) and nighttime temperatures approaching 0 °C (32 °F). In cold deserts, temperatures can be as high as 25 °C and can drop below -30 °C (-22 °F). Subtropical deserts are characterized by low annual precipitation of fewer than 30 cm (12 in) with little monthly variation and lack of predictability in rainfall. In some cases, the annual rainfall can be as low as 2 cm (0.8 in) in subtropical deserts located in central Australia (“the Outback”) and northern Africa.

The vegetation and low animal diversity of this biome is closely related to this low and unpredictable precipitation. Very dry deserts lack perennial vegetation that lives from one year to the next; instead, many plants are annuals that grow quickly and reproduce when rainfall does occur, then they die. Many other plants in these areas are characterized by having a number of adaptations that conserve water, such as deep roots, reduced foliage, and water-storing stems ([Figure 35.15](#)). Seed plants in the desert produce seeds that can be in dormancy for extended periods between rains. Adaptations in desert animals include nocturnal behavior and burrowing.

**Figure 35.15** To reduce water loss, many desert plants have tiny leaves or no leaves at all. The leaves of ocotillo (*Fouquieria splendens*), shown here in the Sonora Desert near Gila Bend, Arizona, appear only after rainfall, and then are shed.

## Chaparral

The chaparral is also called the scrub forest and is found in California, along the Mediterranean Sea, and along the southern coast of Australia (Figure 35.12). The annual rainfall in this biome ranges from 65 cm to 75 cm (25.6–29.5 in), and the majority of the rain falls in the winter. Summers are very dry and many chaparral plants are dormant during the summertime. The chaparral vegetation, shown in Figure 35.16, is dominated by shrubs and is adapted to periodic fires, with some plants producing seeds that only germinate after a hot fire. The ashes left behind after a fire are rich in nutrients like nitrogen that fertilize the soil and promote plant regrowth.

**Figure 35.16** The chaparral is dominated by shrubs. (credit: Miguel Vieira)

## Temperate Grasslands

Temperate grasslands are found throughout central North America, where they are also known as prairies; they are also in Eurasia, where they are known as steppes (Figure 35.12). Temperate grasslands have pronounced annual fluctuations

in temperature with hot summers and cold winters. The annual temperature variation produces specific growing seasons for plants. Plant growth is possible when temperatures are warm enough to sustain plant growth and when ample water is available, which occurs in the spring, summer, and fall. During much of the winter, temperatures are low, and water, which is stored in the form of ice, is not available for plant growth.

Annual precipitation ranges from 25 cm to 75 cm (9.8–29.5 in). Because of relatively lower annual precipitation in temperate grasslands, there are few trees except for those found growing along rivers or streams. The dominant vegetation tends to consist of grasses and some prairies sustain populations of grazing animals **Figure 35.17**. The vegetation is very dense and the soils are fertile because the subsurface of the soil is packed with the roots and rhizomes (underground stems) of these grasses. The roots and rhizomes act to anchor plants into the ground and replenish the organic material (humus) in the soil when they die and decay.

**Figure 35.17** The American bison (*Bison bison*), more commonly called the buffalo, is a grazing mammal that once populated American prairies in huge numbers. (credit: Jack Dykinga, USDA Agricultural Research Service)

Fires, mainly caused by lightning, are a natural disturbance in temperate grasslands. When fire is suppressed in temperate grasslands, the vegetation eventually converts to scrub and dense forests. Often, the restoration or management of temperate grasslands requires the use of controlled burns to suppress the growth of trees and maintain the grasses.

## Temperate Forests

Temperate forests are the most common biome in eastern North America, Western Europe, Eastern Asia, Chile, and New Zealand (**Figure 35.12**). This biome is found throughout mid-latitude regions. Temperatures range between -30 °C and 30 °C (-22 °F to 86 °F) and drop to below freezing on an annual basis. These temperatures mean that temperate forests have defined growing seasons during the spring, summer, and early fall. Precipitation is relatively constant throughout the year and ranges between 75 cm and 150 cm (29.5–59 in).

Because of the moderate annual rainfall and temperatures, deciduous trees are the dominant plant in this biome (**Figure 35.18**). Deciduous trees lose their leaves each fall and remain leafless in the winter. Thus, no photosynthesis occurs in the deciduous trees during the dormant winter period. Each spring, new leaves appear as the temperature increases. Because of the dormant period, the net primary productivity of temperate forests is less than that of tropical wet forests. In addition, temperate forests show less diversity of tree species than tropical wet forest biomes.

**Figure 35.18** Deciduous trees are the dominant plant in the temperate forest. (credit: Oliver Herold)

The trees of the temperate forests leaf out and shade much of the ground; however, this biome is more open than tropical wet forests because trees in the temperate forests do not grow as tall as the trees in tropical wet forests. The soils of the temperate forests are rich in inorganic and organic nutrients. This is due to the thick layer of leaf litter on forest floors. As this leaf litter decays, nutrients are returned to the soil. The leaf litter also protects soil from erosion, insulates the ground, and provides habitats for invertebrates (such as the pill bug or roly-poly, *Armadillidium vulgare*) and their predators, such as the red-backed salamander (*Plethodon cinereus*).

## Boreal Forests

The boreal forest, also known as taiga or coniferous forest, is found south of the Arctic Circle and across most of Canada, Alaska, Russia, and northern Europe (Figure 35.12). This biome has cold, dry winters and short, cool, wet summers. The annual precipitation is from 40 cm to 100 cm (15.7–39 in) and usually takes the form of snow. Little evaporation occurs because of the cold temperatures.

The long and cold winters in the boreal forest have led to the predominance of cold-tolerant cone-bearing plants. These are evergreen coniferous trees like pines, spruce, and fir, which retain their needle-shaped leaves year-round. Evergreen trees can photosynthesize earlier in the spring than deciduous trees because less energy from the sun is required to warm a needle-like leaf than a broad leaf. This benefits evergreen trees, which grow faster than deciduous trees in the boreal forest. In addition, soils in boreal forest regions tend to be acidic with little available nitrogen. Leaves are a nitrogen-rich structure and deciduous trees must produce a new set of these nitrogen-rich structures each year. Therefore, coniferous trees that retain nitrogen-rich needles may have a competitive advantage over the broad-leaved deciduous trees.

The net primary productivity of boreal forests is lower than that of temperate forests and tropical wet forests. The aboveground biomass of boreal forests is high because these slow-growing tree species are long lived and accumulate standing biomass over time. Plant species diversity is less than that seen in temperate forests and tropical wet forests. Boreal forests lack the pronounced elements of the layered forest structure seen in tropical wet forests. The structure of a boreal forest is often only a tree layer and a ground layer (Figure 35.19). When conifer needles are dropped, they decompose more slowly than broad leaves; therefore, fewer nutrients are returned to the soil to fuel plant growth.

**Figure 35.19** The boreal forest (taiga) has low lying plants and conifer trees. (credit: L.B. Brubaker)

## Arctic Tundra

The Arctic tundra lies north of the subarctic boreal forest and is located throughout the Arctic regions of the northern hemisphere (Figure 35.12). The average winter temperature is  $-34^{\circ}\text{C}$  ( $-34^{\circ}\text{F}$ ) and the average summer temperature is from  $3^{\circ}\text{C}$  to  $12^{\circ}\text{C}$  ( $37^{\circ}\text{F}$ – $52^{\circ}\text{F}$ ). Plants in the arctic tundra have a very short growing season of approximately 10–12 weeks. However, during this time, there are almost 24 hours of daylight and plant growth is rapid. The annual precipitation of the Arctic tundra is very low with little annual variation in precipitation. And, as in the boreal forests, there is little evaporation due to the cold temperatures.

Plants in the Arctic tundra are generally low to the ground (Figure 35.20). There is little species diversity, low net primary productivity, and low aboveground biomass. The soils of the Arctic tundra may remain in a perennially frozen state referred to as **permafrost**. The permafrost makes it impossible for roots to penetrate deep into the soil and slows the decay of organic matter, which inhibits the release of nutrients from organic matter. During the growing season, the ground of the Arctic tundra can be completely covered with plants or lichens.

**Figure 35.20** Low-growing plants such as shrub willow dominate the tundra landscape, shown here in the Arctic National Wildlife Refuge. (credit: USFWS Arctic National Wildlife Refuge)

Watch this **Assignment Discovery: Biomes** video (<http://openstaxcollege.org/l/biomes>) for an overview of biomes. To explore further, select one of the biomes on the extended playlist: desert, savanna, temperate forest, temperate grassland, tropic, tundra.

Which of the following biomes is characterized by low precipitation, cactus, hardy shrubs, and high temperatures?

- a. tundra
- b. chapparal
- c. desert
- d. boreal forest

## science practices CONNECTION for AP<sup>®</sup> Courses

### Activity

For five different terrestrial biomes, create a visual representation to describe each biome and factors that affect its climate. What unique adaptations help plants and animals survive in each biome?

### Think About It

In what ways are the subtropical desert and the Arctic tundra similar?

## 35.4 | Aquatic Biomes

In this section, you will explore the following questions:

- What are the effects of abiotic factors on the composition of plant and animal communities in aquatic biomes?
- What are the similarities and differences among the ocean zones?
- What are characteristics of standing water and flowing water freshwater biomes?

### Connection for AP<sup>®</sup> Courses

Much of the information in this section is outside the scope for AP<sup>®</sup>. You do not need to memorize a list of Earth's different aquatic biomes and their descriptive features. However, we learned previously that organisms interact with each other and with their environments to move matter and energy. Aquatic biomes are ripe with these interactions. Coral reefs, for example, exhibit rich biodiversity.

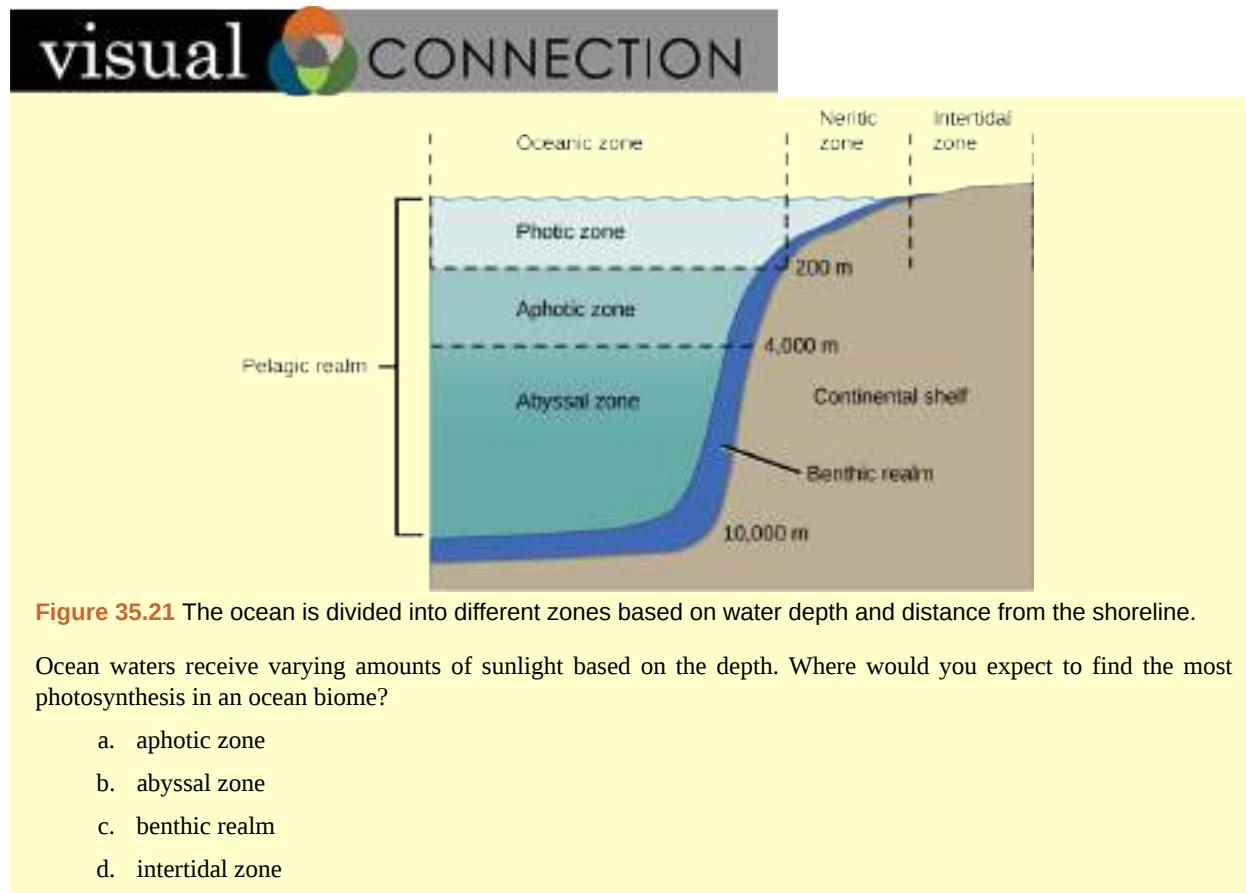

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 of the AP<sup>®</sup> Biology Curriculum Framework. The AP<sup>®</sup> Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

## Abiotic Factors Influencing Aquatic Biomes

Like terrestrial biomes, aquatic biomes are influenced by a series of abiotic factors. The aquatic medium—water—has different physical and chemical properties than air, however. Even if the water in a pond or other body of water is perfectly clear (there are no suspended particles), water, on its own, absorbs light. As one descends into a deep body of water, there will eventually be a depth which the sunlight cannot reach. While there are some abiotic and biotic factors in a terrestrial ecosystem that might obscure light (like fog, dust, or insect swarms), usually these are not permanent features of the environment. The importance of light in aquatic biomes is central to the communities of organisms found in both freshwater and marine ecosystems. In freshwater systems, stratification due to differences in density is perhaps the most critical abiotic factor and is related to the energy aspects of light. The thermal properties of water (rates of heating and cooling) are significant to the function of marine systems and have major impacts on global climate and weather patterns. Marine systems are also influenced by large-scale physical water movements, such as currents; these are less important in most freshwater lakes.

The ocean is categorized by several areas or zones (**Figure 35.21**). All of the ocean's open water is referred to as the **pelagic realm** (or zone). The **benthic realm** (or zone) extends along the ocean bottom from the shoreline to the deepest parts of the ocean floor. Within the pelagic realm is the **photic zone**, which is the portion of the ocean that light can penetrate (approximately 200 m or 650 ft). At depths greater than 200 m, light cannot penetrate; thus, this is referred to as the **aphotic zone**. The majority of the ocean is aphotic and lacks sufficient light for photosynthesis. The deepest part of the ocean, the Challenger Deep (in the Mariana Trench, located in the western Pacific Ocean), is about 11,000 m (about 6.8 mi) deep. To give some perspective on the depth of this trench, the ocean is, on average, 4267 m or 14,000 ft deep. These realms and zones are relevant to freshwater lakes as well.

**Figure 35.21** The ocean is divided into different zones based on water depth and distance from the shoreline.

Ocean waters receive varying amounts of sunlight based on the depth. Where would you expect to find the most photosynthesis in an ocean biome?

- a. aphotic zone
- b. abyssal zone
- c. benthic realm
- d. intertidal zone

## Marine Biomes

The ocean is the largest marine biome. It is a continuous body of salt water that is relatively uniform in chemical composition; it is a weak solution of mineral salts and decayed biological matter. Within the ocean, coral reefs are a second kind of marine biome. Estuaries, coastal areas where salt water and fresh water mix, form a third unique marine biome.

### Ocean

The physical diversity of the ocean is a significant influence on plants, animals, and other organisms. The ocean is categorized into different zones based on how far light reaches into the water. Each zone has a distinct group of species adapted to the biotic and abiotic conditions particular to that zone.

The **intertidal zone**, which is the zone between high and low tide, is the oceanic region that is closest to land (**Figure 35.21**). Generally, most people think of this portion of the ocean as a sandy beach. In some cases, the intertidal zone is indeed a sandy beach, but it can also be rocky or muddy. The intertidal zone is an extremely variable environment because of tides. Organisms are exposed to air and sunlight at low tide and are underwater most of the time, especially during high tide. Therefore, living things that thrive in the intertidal zone are adapted to being dry for long periods of time. The shore of the intertidal zone is also repeatedly struck by waves, and the organisms found there are adapted to withstand damage from the pounding action of the waves (**Figure 35.22**). The exoskeletons of shoreline crustaceans (such as the shore crab, *Carcinus maenas*) are tough and protect them from desiccation (drying out) and wave damage. Another consequence of the pounding waves is that few algae and plants establish themselves in the constantly moving rocks, sand, or mud.

**Figure 35.22** Sea urchins, mussel shells, and starfish are often found in the intertidal zone, shown here in Kachemak Bay, Alaska. (credit: NOAA)

The **neritic zone** (Figure 35.21) extends from the intertidal zone to depths of about 200 m (or 650 ft) at the edge of the continental shelf. Since light can penetrate this depth, photosynthesis can occur in the neritic zone. The water here contains silt and is well-oxygenated, low in pressure, and stable in temperature. Phytoplankton and floating *Sargassum* (a type of free-floating marine seaweed) provide a habitat for some sea life found in the neritic zone. Zooplankton, protists, small fishes, and shrimp are found in the neritic zone and are the base of the food chain for most of the world's fisheries.

Beyond the neritic zone is the open ocean area known as the **oceanic zone** (Figure 35.21). Within the oceanic zone there is thermal stratification where warm and cold waters mix because of ocean currents. Abundant plankton serve as the base of the food chain for larger animals such as whales and dolphins. Nutrients are scarce and this is a relatively less productive part of the marine biome. When photosynthetic organisms and the protists and animals that feed on them die, their bodies fall to the bottom of the ocean where they remain; unlike freshwater lakes, the open ocean lacks a process for bringing the organic nutrients back up to the surface. The majority of organisms in the aphotic zone include sea cucumbers (phylum Echinodermata) and other organisms that survive on the nutrients contained in the dead bodies of organisms in the photic zone.

Beneath the pelagic zone is the benthic realm, the deepwater region beyond the continental shelf (Figure 35.21). The bottom of the benthic realm is comprised of sand, silt, and dead organisms. Temperature decreases, remaining above freezing, as water depth increases. This is a nutrient-rich portion of the ocean because of the dead organisms that fall from the upper layers of the ocean. Because of this high level of nutrients, a diversity of fungi, sponges, sea anemones, marine worms, sea stars, fishes, and bacteria exist.

The deepest part of the ocean is the **abyssal zone**, which is at depths of 4000 m or greater. The abyssal zone (Figure 35.21) is very cold and has very high pressure, high oxygen content, and low nutrient content. There are a variety of invertebrates and fishes found in this zone, but the abyssal zone does not have plants because of the lack of light. Hydrothermal vents are found primarily in the abyssal zone; chemosynthetic bacteria utilize the hydrogen sulfide and other minerals emitted from the vents. These chemosynthetic bacteria use the hydrogen sulfide as an energy source and serve as the base of the food chain found in the abyssal zone.

### Coral Reefs

**Coral reefs** are ocean ridges formed by marine invertebrates living in warm shallow waters within the photic zone of the ocean. They are found within 30° north and south of the equator. The Great Barrier Reef is a well-known reef system located several miles off the northeastern coast of Australia. Other coral reef systems are fringing islands, which are directly adjacent to land, or atolls, which are circular reef systems surrounding a former landmass that is now underwater. The coral organisms (members of phylum Cnidaria) are colonies of saltwater polyps that secrete a calcium carbonate skeleton. These calcium-rich skeletons slowly accumulate, forming the underwater reef (Figure 35.23). Corals found in shallower waters (at a depth of approximately 60 m or about 200 ft) have a mutualistic relationship with photosynthetic unicellular algae. The relationship provides corals with the majority of the nutrition and the energy they require. The waters in which these corals live are nutritionally poor and, without this mutualism, it would not be possible for large corals to grow. Some corals living in deeper and colder water do not have a mutualistic relationship with algae; these corals attain energy and nutrients using stinging cells on their tentacles to capture prey.

Watch this **National Oceanic and Atmospheric Administration (NOAA) video** ([http://openstaxcollege.org/l/marine\\_biology](http://openstaxcollege.org/l/marine_biology)) to see marine ecologist Dr. Peter Etnoyer discusses his research on coral organisms.

Corals are found in deep seas. How do marine ecologists study deep sea corals without having to destroy their habitat?

- a. deep sea diving
- b. multibeam echo sounder
- c. sonar
- d. laser

It is estimated that more than 4,000 fish species inhabit coral reefs. These fishes can feed on coral, the **cryptofauna** (invertebrates found within the calcium carbonate substrate of the coral reefs), or the seaweed and algae that are associated with the coral. In addition, some fish species inhabit the boundaries of a coral reef; these species include **predators**, herbivores, or **planktivores**. Predators are animal species that hunt and are carnivores or “flesh eaters.” Herbivores eat plant material, and planktivores eat plankton.

**Figure 35.23** Coral reefs are formed by the calcium carbonate skeletons of coral organisms, which are marine invertebrates in the phylum Cnidaria. (credit: Terry Hughes)

# evolution CONNECTION

## Global Decline of Coral Reefs

It takes a long time to build a coral reef. The animals that create coral reefs have evolved over millions of years, continuing to slowly deposit the calcium carbonate that forms their characteristic ocean homes. Bathed in warm tropical waters, the coral animals and their symbiotic algal partners evolved to survive at the upper limit of ocean water temperature.

Together, climate change and human activity pose dual threats to the long-term survival of the world's coral reefs. As global warming due to fossil fuel emissions raises ocean temperatures, coral reefs are suffering. The excessive warmth causes the reefs to expel their symbiotic, food-producing algae, resulting in a phenomenon known as bleaching. When bleaching occurs, the reefs lose much of their characteristic color as the algae and the coral animals die if loss of the symbiotic zooxanthellae is prolonged.

Rising levels of atmospheric carbon dioxide further threaten the corals in other ways; as CO<sub>2</sub> dissolves in ocean waters, it lowers the pH and increases ocean acidity. As acidity increases, it interferes with the calcification that normally occurs as coral animals build their calcium carbonate homes.

When a coral reef begins to die, species diversity plummets as animals lose food and shelter. Coral reefs are also economically important tourist destinations, so the decline of coral reefs poses a serious threat to coastal economies.

Human population growth has damaged corals in other ways, too. As human coastal populations increase, the runoff of sediment and agricultural chemicals has increased, too, causing some of the once-clear tropical waters to become cloudy. At the same time, overfishing of popular fish species has allowed the predator species that eat corals to go unchecked.

Although a rise in global temperatures of 1–2°C (a conservative scientific projection) in the coming decades may not seem large, it is very significant to this biome. When change occurs rapidly, species can become extinct before evolution leads to new adaptations. Many scientists believe that global warming, with its rapid (in terms of evolutionary time) and inexorable increases in temperature, is tipping the balance beyond the point at which many of the world's coral reefs can recover.

What are the effects of global climate change and increasing levels of carbon dioxide on the coral reefs? How does it affect the local ecosystem?

- a. Due to rising temperature, coral reefs lose their symbiotic partner, the algae, in the process called bleaching. Rising CO<sub>2</sub> changes the pH of water, which interferes with calcification. Animals whose source of food is coral reefs also decline in numbers.
- b. Due to rising temperature the hard calcium carbonate skeleton of coral reefs is destroyed due to a process called bleaching. Rising CO<sub>2</sub> changes pH of water which interferes with calcification. Animals whose source of food is coral reefs also decline in numbers.
- c. Due to rising temperature, coral reefs lose their symbiotic partner, the algae, in the process called ocean acidification. Rising CO<sub>2</sub> changes the pH of water, which interferes with calcification. Animals whose source of food is coral reefs also decline in numbers.
- d. Due to rising temperature, coral reefs lose their symbiotic partner, the algae. Rising CO<sub>2</sub> changes the pH of water through the process called bleaching. Animals whose source of food is coral reefs also decline in numbers.

## Estuaries: Where the Ocean Meets Fresh Water

**Estuaries** are biomes that occur where a source of fresh water, such as a river, meets the ocean. Therefore, both fresh water and salt water are found in the same vicinity; mixing results in a diluted (brackish) saltwater. Estuaries form protected areas where many of the young offspring of crustaceans, mollusks, and fish begin their lives. Salinity is a very important factor that influences the organisms and the adaptations of the organisms found in estuaries. The salinity of estuaries varies and is based on the rate of flow of its freshwater sources. Once or twice a day, high tides bring salt water into the estuary. Low tides occurring at the same frequency reverse the current of salt water.

The short-term and rapid variation in salinity due to the mixing of fresh water and salt water is a difficult physiological

challenge for the plants and animals that inhabit estuaries. Many estuarine plant species are halophytes: plants that can tolerate salty conditions. Halophytic plants are adapted to deal with the salinity resulting from saltwater on their roots or from sea spray. In some halophytes, filters in the roots remove the salt from the water that the plant absorbs. Other plants are able to pump oxygen into their roots. Animals, such as mussels and clams (phylum Mollusca), have developed behavioral adaptations that expend a lot of energy to function in this rapidly changing environment. When these animals are exposed to low salinity, they stop feeding, close their shells, and switch from aerobic respiration (in which they use gills) to anaerobic respiration (a process that does not require oxygen). When high tide returns to the estuary, the salinity and oxygen content of the water increases, and these animals open their shells, begin feeding, and return to aerobic respiration.

**everyday CONNECTION for AP<sup>®</sup> Courses**

**Figure 35.24** Estuaries are formed when marine water and fresh water meet. As a result, the water in estuaries vary widely in salinity. Organisms living in estuaries, such as the mangroves pictured here, must be able to tolerate a wide variation of salinity. (credit: Moni3, Wikimedia Commons)

The spring and fall turnovers are important processes in freshwater lakes that act to move nutrients and water from the bottom to the top. Explain how this is different in temperate regions as compared to the tropics.

- a. Spring turnover occurs in tropical lakes, but not in temperate lakes. Stratification occurs in temperate lakes.
- b. Temperate lakes do not freeze so they do not undergo spring turnover or stratification.
- c. Stratification and spring turnover occur in tropical lakes. Temperate lakes do not freeze so they do not undergo spring turnover.
- d. Stratification and spring turnover occur in temperate lakes. Tropical lakes do not freeze so they do not undergo spring turnover.

## Freshwater Biomes

Freshwater biomes include lakes and ponds (standing water) as well as rivers and streams (flowing water). They also include wetlands, which will be discussed later. Humans rely on freshwater biomes to provide aquatic resources for drinking water, crop irrigation, sanitation, and industry. These various roles and human benefits are referred to as **ecosystem services**. Lakes and ponds are found in terrestrial landscapes and are, therefore, connected with abiotic and biotic factors influencing these terrestrial biomes.

### Lakes and Ponds

Lakes and ponds can range in area from a few square meters to thousands of square kilometers. Temperature is an important abiotic factor affecting living things found in lakes and ponds. In the summer, thermal stratification of lakes and ponds occurs when the upper layer of water is warmed by the sun and does not mix with deeper, cooler water. Light can penetrate within the photic zone of the lake or pond. Phytoplankton (algae and cyanobacteria) are found here and carry out photosynthesis, providing the base of the food web of lakes and ponds. Zooplankton, such as rotifers and small crustaceans, consume these phytoplankton. At the bottom of lakes and ponds, bacteria in the aphotic zone break down dead organisms that sink to the bottom.

Nitrogen and phosphorus are important limiting nutrients in lakes and ponds. Because of this, they are determining factors in the amount of phytoplankton growth in lakes and ponds. When there is a large input of nitrogen and phosphorus (from sewage and runoff from fertilized lawns and farms, for example), the growth of algae skyrockets, resulting in a large accumulation of algae called an **algal bloom**. Algal blooms (Figure 35.25) can become so extensive that they reduce light penetration in water. As a result, the lake or pond becomes aphotic and photosynthetic plants cannot survive. When the algae die and decompose, severe oxygen depletion of the water occurs. Fishes and other organisms that require oxygen are then more likely to die, and resulting dead zones are found across the globe. Lake Erie and the Gulf of Mexico represent freshwater and marine habitats where phosphorus control and storm water runoff pose significant environmental challenges.

**Figure 35.25** The uncontrolled growth of algae in this lake has resulted in an algal bloom. (credit: Jeremy Nettleton)

### Rivers and Streams

Rivers and streams are continuously moving bodies of water that carry large amounts of water from the source, or headwater, to a lake or ocean. The largest rivers include the Nile River in Africa, the Amazon River in South America, and the Mississippi River in North America.

Abiotic features of rivers and streams vary along the length of the river or stream. Streams begin at a point of origin referred to as **source water**. The source water is usually cold, low in nutrients, and clear. The **channel** (the width of the river or stream) is narrower than at any other place along the length of the river or stream. Because of this, the current is often faster here than at any other point of the river or stream.

The fast-moving water results in minimal silt accumulation at the bottom of the river or stream; therefore, the water is clear. Photosynthesis here is mostly attributed to algae that are growing on rocks; the swift current inhibits the growth of phytoplankton. An additional input of energy can come from leaves or other organic material that falls into the river or stream from trees and other plants that border the water. When the leaves decompose, the organic material and nutrients in the leaves are returned to the water. Plants and animals have adapted to this fast-moving water. For instance, leeches (phylum Annelida) have elongated bodies and suckers on both ends. These suckers attach to the substrate, keeping the leech anchored in place. Freshwater trout species (phylum Chordata) are an important predator in these fast-moving rivers and streams.

As the river or stream flows away from the source, the width of the channel gradually widens and the current slows. This slow-moving water, caused by the gradient decrease and the volume increase as tributaries unite, has more sedimentation. Phytoplankton can also be suspended in slow-moving water. Therefore, the water will not be as clear as it is near the source. The water is also warmer. Worms (phylum Annelida) and insects (phylum Arthropoda) can be found burrowing into the mud. The higher order predator vertebrates (phylum Chordata) include waterfowl, frogs, and fishes. These predators must find food in these slow moving, sometimes murky, waters and, unlike the trout in the waters at the source, these vertebrates may not be able to use vision as their primary sense to find food. Instead, they are more likely to use taste or chemical cues to find prey.

### Wetlands

Wetlands are environments in which the soil is either permanently or periodically saturated with water. Wetlands are different from lakes because wetlands are shallow bodies of water whereas lakes vary in depth. **Emergent vegetation** consists of wetland plants that are rooted in the soil but have portions of leaves, stems, and flowers extending above the water's surface. There are several types of wetlands including marshes, swamps, bogs, mudflats, and salt marshes (Figure 35.26). The three shared characteristics among these types—what makes them wetlands—are their hydrology, hydrophytic vegetation, and hydric soils.

**Figure 35.26** Located in southern Florida, Everglades National Park is vast array of wetland environments, including sawgrass marshes, cypress swamps, and estuarine mangrove forests. Here, a great egret walks among cypress trees. (credit: NPS)

Freshwater marshes and swamps are characterized by slow and steady water flow. Bogs develop in depressions where water flow is low or nonexistent. Bogs usually occur in areas where there is a clay bottom with poor percolation. Percolation is the movement of water through the pores in the soil or rocks. The water found in a bog is stagnant and oxygen depleted because the oxygen that is used during the decomposition of organic matter is not replaced. As the oxygen in the water is depleted, decomposition slows. This leads to organic acids and other acids building up and lowering the pH of the water. At a lower pH, nitrogen becomes unavailable to plants. This creates a challenge for plants because nitrogen is an important limiting resource. Some types of bog plants (such as sundews, pitcher plants, and Venus flytraps) capture insects and extract the nitrogen from their bodies. Bogs have low net primary productivity because the water found in bogs has low levels of nitrogen and oxygen.

## 35.5 | Climate and the Effects of Global Climate Change

In this section, you will explore the following questions:

- What is global climate change?
- What are the effects of the Industrial Revolution on global atmospheric carbon dioxide concentration?
- What are examples of natural factors that affect long-term global climate?
- What are examples of greenhouse gases and their role(s) in the greenhouse effect?

### Connection for AP® Courses

Both terrestrial and aquatic biomes are affected by global conditions, such as climate. Scientists have noted marked changes that have altered global weather patterns. Collectively, these changes are called **global climate change** and include a worldwide increase in temperature due primarily to rising levels of atmospheric carbon dioxide. There are several causes of global climate change, including human activity. The effects of human activity on other aspects of ecosystems will be explored in the Conservation Biology and Biodiversity chapter.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

#### Big Idea 4

Biological systems interact, and these systems and their interactions possess complex properties.

|                                   |                                                                                                                         |

| <b>Learning Objective</b>         | <b>4.16</b> The student is able to predict the effects of a change of matter or energy availability on communities.     |

## Climate and Weather

A common misconception about global climate change is that a specific weather event occurring in a particular region (for example, a very cool week in June in central Indiana) is evidence of global climate change. However, a cold week in June is a weather-related event and not a climate-related one. These misconceptions often arise because of confusion over the terms climate and weather.

**Climate** refers to the long-term, predictable atmospheric conditions of a specific area. The climate of a biome is characterized by having consistent temperature and annual rainfall ranges. Climate does not address the amount of rain that fell on one particular day in a biome or the colder-than-average temperatures that occurred on one day. In contrast, **weather** refers to the conditions of the atmosphere during a short period of time. Weather forecasts are usually made for 48-hour cycles. Long-range weather forecasts are available but can be unreliable.

To better understand the difference between climate and weather, imagine that you are planning an outdoor event in northern Wisconsin. You would be thinking about *climate* when you plan the event in the summer rather than the winter because you have long-term knowledge that any given Saturday in the months of May to August would be a better choice for an outdoor event in Wisconsin than any given Saturday in January. However, you cannot determine the specific day that the event should be held on because it is difficult to accurately predict the weather on a specific day. Climate can be considered “average” weather.

## Global Climate Change

Climate change can be understood by approaching three areas of study:

- current and past global climate change
- causes of past and present-day global climate change
- ancient and current results of climate change

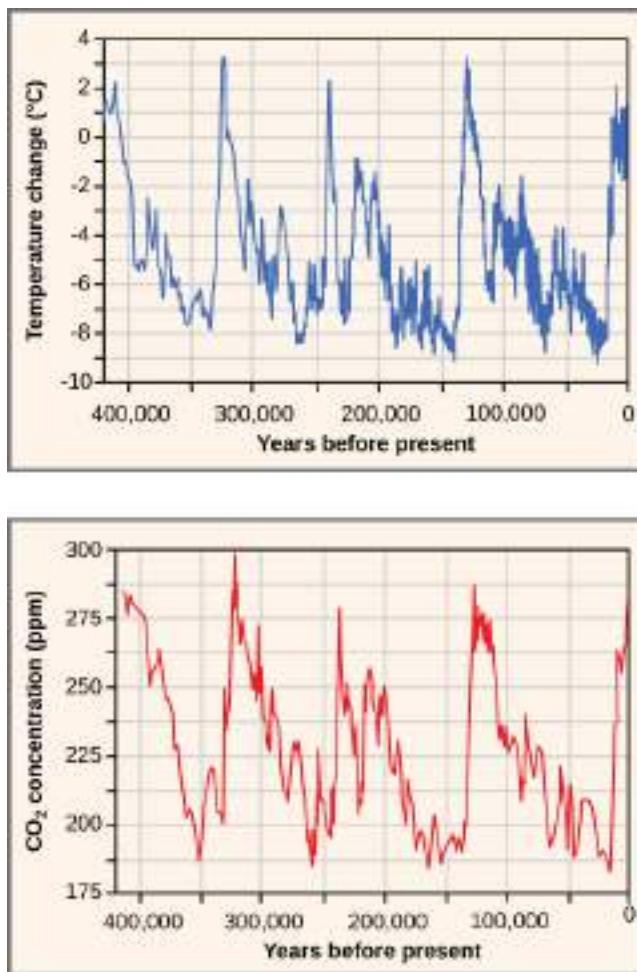

It is helpful to keep these three different aspects of climate change clearly separated when consuming media reports about global climate change. It is common for reports and discussions about global climate change to confuse the data showing that Earth’s climate is changing with the factors that drive this climate change.

### Evidence for Global Climate Change

Since scientists cannot go back in time to directly measure climatic variables, such as average temperature and precipitation, they must instead indirectly measure temperature. To do this, scientists rely on historical evidence of Earth’s past climate.

Antarctic ice cores are a key example of such evidence. These ice cores are samples of polar ice obtained by means of drills that reach thousands of meters into ice sheets or high mountain glaciers. Viewing the ice cores is like traveling backwards through time; the deeper the sample, the earlier the time period. Trapped within the ice are bubbles of air and other biological evidence that can reveal temperature and carbon dioxide data. Antarctic ice cores have been collected and analyzed to indirectly estimate the temperature of the Earth over the past 400,000 years ([Figure 35.27a](#)). The 0 °C on this graph refers to the long-term average. Temperatures that are greater than 0 °C exceed Earth’s long-term average temperature. Conversely, temperatures that are less than 0 °C are less than Earth’s average temperature. This figure shows that there have been periodic cycles of increasing and decreasing temperature.

Before the late 1800s, the Earth has been as much as 9 °C cooler and about 3 °C warmer. Note that the graph in [Figure 35.27b](#) shows that the atmospheric concentration of carbon dioxide has also risen and fallen in periodic cycles; note the relationship between carbon dioxide concentration and temperature. [Figure 35.27b](#) shows that carbon dioxide levels in the atmosphere have historically cycled between 180 and 300 parts per million (ppm) by volume.

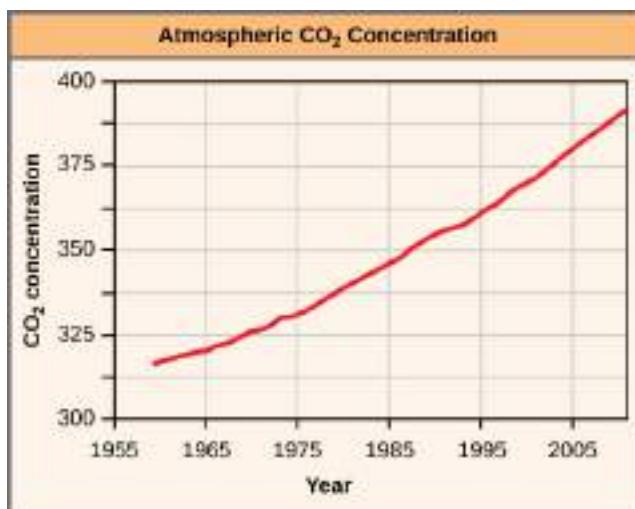

**Figure 35.27** Ice at the Russian Vostok station in East Antarctica was laid down over the course 420,000 years and reached a depth of over 3,000 m. By measuring the amount of CO<sub>2</sub> trapped in the ice, scientists have determined past atmospheric CO<sub>2</sub> concentrations. Temperatures relative to modern day were determined from the amount of deuterium (an isotope of hydrogen) present.

**Figure 35.27a** does not show the last 2,000 years with enough detail to compare the changes of Earth's temperature during the last 400,000 years with the temperature change that has occurred in the more recent past. Two significant temperature anomalies, or irregularities, have occurred in the last 2000 years. These are the Medieval Climate Anomaly (or the Medieval Warm Period) and the Little Ice Age. A third temperature anomaly aligns with the Industrial Era. The Medieval Climate Anomaly occurred between 900 and 1300 AD. During this time period, many climate scientists think that slightly warmer weather conditions prevailed in many parts of the world; the higher-than-average temperature changes varied between 0.10 °C and 0.20 °C above the norm. Although 0.10 °C does not seem large enough to produce any noticeable change, it did free seas of ice. Because of this warming, the Vikings were able to colonize Greenland.

The Little Ice Age was a cold period that occurred between 1550 AD and 1850 AD. During this time, a slight cooling of a little less than 1 °C was observed in North America, Europe, and possibly other areas of the Earth. This 1 °C change in global temperature is a seemingly small deviation in temperature (as was observed during the Medieval Climate Anomaly); however, it also resulted in noticeable changes. Historical accounts reveal a time of exceptionally harsh winters with much snow and frost.

The Industrial Revolution, which began around 1750, was characterized by changes in much of human society. Advances in agriculture increased the food supply, which improved the standard of living for people in Europe and the United States. New technologies were invented and provided jobs and cheaper goods. These new technologies were powered using fossil fuels, especially coal. The Industrial Revolution starting in the early nineteenth century ushered in the beginning of the Industrial Era. When a fossil fuel is burned, carbon dioxide is released. With the beginning of the Industrial Era, atmospheric carbon dioxide began to rise (**Figure 35.28**).

**Figure 35.28** The atmospheric concentration of CO<sub>2</sub> has risen steadily since the beginning of industrialization.

### Current and Past Drivers of Global Climate Change

Since it is not possible to go back in time to directly observe and measure climate, scientists use indirect evidence to determine the drivers, or factors, that may be responsible for climate change. The indirect evidence includes data collected using ice cores, boreholes (a narrow shaft bored into the ground), tree rings, glacier lengths, pollen remains, and ocean sediments. The data shows a correlation between the timing of temperature changes and drivers of climate change: before the Industrial Era (pre-1780), there were three drivers of climate change that were not related to human activity or atmospheric gases. The first of these is the Milankovitch cycles. The **Milankovitch cycles** describe the effects of slight changes in the Earth's orbit on Earth's climate. The length of the Milankovitch cycles ranges between 19,000 and 100,000 years. In other words, one could expect to see some predictable changes in the Earth's climate associated with changes in the Earth's orbit at a minimum of every 19,000 years.

The variation in the sun's intensity is the second natural factor responsible for climate change. **Solar intensity** is the amount of solar power or energy the sun emits in a given amount of time. There is a direct relationship between solar intensity and temperature. As solar intensity increases (or decreases), the Earth's temperature correspondingly increases (or decreases). Changes in solar intensity have been proposed as one of several possible explanations for the Little Ice Age.

Finally, volcanic eruptions are a third natural driver of climate change. Volcanic eruptions can last a few days, but the solids and gases released during an eruption can influence the climate over a period of a few years, causing short-term climate changes. The gases and solids released by volcanic eruptions can include carbon dioxide, water vapor, sulfur dioxide, hydrogen sulfide, hydrogen, and carbon monoxide. Generally, volcanic eruptions cool the climate. This occurred in 1783 when volcanos in Iceland erupted and caused the release of large volumes of sulfuric oxide. This led to **haze-effect cooling**, a global phenomenon that occurs when dust, ash, or other suspended particles block out sunlight and trigger lower global temperatures as a result; haze-effect cooling usually extends for one or more years. In Europe and North America, haze-effect cooling produced some of the lowest average winter temperatures on record in 1783 and 1784.

Greenhouse gases are probably the most significant drivers of the climate. When heat energy from the sun strikes the Earth, gases known as **greenhouse gases** trap the heat in the atmosphere, as do the glass panes of a greenhouse keep heat from escaping. The greenhouse gases that affect Earth include carbon dioxide, methane, water vapor, nitrous oxide, and ozone. Approximately half of the radiation from the sun passes through these gases in the atmosphere and strikes the Earth. This radiation is converted into thermal radiation on the Earth's surface, and then a portion of that energy is re-radiated back into the atmosphere. Greenhouse gases, however, reflect much of the thermal energy back to the Earth's surface. The more greenhouse gases there are in the atmosphere, the more thermal energy is reflected back to the Earth's surface. Greenhouse gases absorb and emit radiation and are an important factor in the **greenhouse effect**: the warming of Earth due to carbon dioxide and other greenhouse gases in the atmosphere.

Evidence supports the relationship between atmospheric concentrations of carbon dioxide and temperature: as carbon dioxide rises, global temperature rises. Since 1950, the concentration of atmospheric carbon dioxide has increased from about 280 ppm to 382 ppm in 2006. In 2011, the atmospheric carbon dioxide concentration was 392 ppm. However, the planet would not be inhabitable by current life forms if water vapor did not produce its drastic greenhouse warming effect.

Scientists look at patterns in data and try to explain differences or deviations from these patterns. The atmospheric carbon dioxide data reveal a historical pattern of carbon dioxide increasing and decreasing, cycling between a low of 180 ppm and a high of 300 ppm. Scientists have concluded that it took around 50,000 years for the atmospheric carbon dioxide level to

increase from its low minimum concentration to its higher maximum concentration. However, starting recently, atmospheric carbon dioxide concentrations have increased beyond the historical maximum of 300 ppm. The current increases in atmospheric carbon dioxide have happened very quickly—in a matter of hundreds of years rather than thousands of years. What is the reason for this difference in the rate of change and the amount of increase in carbon dioxide? A key factor that must be recognized when comparing the historical data and the current data is the presence of modern human society; no other driver of climate change has yielded changes in atmospheric carbon dioxide levels at this rate or to this magnitude.

Human activity releases carbon dioxide and methane, two of the most important greenhouse gases, into the atmosphere in several ways. The primary mechanism that releases carbon dioxide is the burning of fossil fuels, such as gasoline, coal, and natural gas (**Figure 35.29**). Deforestation, cement manufacture, animal agriculture, the clearing of land, and the burning of forests are other human activities that release carbon dioxide. Methane ( $\text{CH}_4$ ) is produced when bacteria break down organic matter under anaerobic conditions. Anaerobic conditions can happen when organic matter is trapped underwater (such as in rice paddies) or in the intestines of herbivores. Methane can also be released from natural gas fields and the decomposition that occurs in landfills. Another source of methane is the melting of clathrates. **Clathrates** are frozen chunks of ice and methane found at the bottom of the ocean. When water warms, these chunks of ice melt and methane is released. As the ocean's water temperature increases, the rate at which clathrates melt is increasing, releasing even more methane. This leads to increased levels of methane in the atmosphere, which further accelerates the rate of global warming. This is an example of the positive feedback loop that is leading to the rapid rate of increase of global temperatures.

**Figure 35.29** The burning of fossil fuels in industry and by vehicles releases carbon dioxide and other greenhouse gases into the atmosphere. (credit: "Pöllö"/Wikimedia Commons)

## Documented Results of Climate Change: Past and Present

Scientists have geological evidence of the consequences of long-ago climate change. Modern-day phenomena such as retreating glaciers and melting polar ice cause a continual rise in sea level. Meanwhile, changes in climate can negatively affect organisms.

### **Geological Climate Change**

Global warming has been associated with at least one planet-wide extinction event during the geological past. The Permian extinction event occurred about 251 million years ago toward the end of the roughly 50-million-year-long geological time span known as the Permian period. This geologic time period was one of the three warmest periods in Earth's geologic history. Scientists estimate that approximately 70 percent of the terrestrial plant and animal species and 84 percent of marine species became extinct, vanishing forever near the end of the Permian period. Organisms that had adapted to wet and warm climatic conditions, such as annual rainfall of 300–400 cm (118–157 in) and 20 °C–30 °C (68 °F–86 °F) in the tropical wet forest, may not have been able to survive the Permian climate change.

Watch this **NASA video** ([http://openstaxcollege.org/l/climate\\_plants](http://openstaxcollege.org/l/climate_plants)) to discover the mixed effects of global warming on plant growth. While scientists found that warmer temperatures in the 1980s and 1990s caused an increase in plant productivity, this advantage has since been counteracted by more frequent droughts.

What impact does climate change have on plants?

- Warmer temperatures extend the growing season of plants, which increases their water requirement throughout the season. Once the growing season ends, shorter, milder winters fail to kill pests increasing the risk of large, damaging infestations in subsequent seasons.
- Warmer temperatures extend growing season of plants, which increases their nutrient requirements throughout the season. The nutrient requirements are not met once the growing season ends, increasing the risk of low productivity.
- Warmer temperatures reduce the growing season of plants, which increase the risk of low productivity. Once the growing season ends, shorter, milder winters fail to kill pests increasing the risk of damaging infestations in subsequent seasons, which also leads to low productivity.
- Warmer temperatures reduce the growing season of plants, which increase the risk of low productivity. Once the growing season ends, milder and shorter winters fail to provide sufficient nutrients to plants increasing the risk of plant death.

### Present Climate Change

A number of global events have occurred that may be attributed to climate change during our lifetimes. Glacier National Park in Montana is undergoing the retreat of many of its glaciers, a phenomenon known as glacier recession. In 1850, the area contained approximately 150 glaciers. By 2010, however, the park contained only about 24 glaciers greater than 25 acres in size. One of these glaciers is the Grinnell Glacier (Figure 35.30) at Mount Gould. Between 1966 and 2005, the size of Grinnell Glacier shrank by 40 percent. Similarly, the mass of the ice sheets in Greenland and the Antarctic is decreasing: Greenland lost 150–250 km<sup>3</sup> of ice per year between 2002 and 2006. In addition, the size and thickness of the Arctic sea ice is decreasing.

**Figure 35.30** The effect of global warming can be seen in the continuing retreat of Grinnell Glacier. The mean annual temperature in the park has increased 1.33 °C since 1900. The loss of a glacier results in the loss of summer meltwaters, sharply reducing seasonal water supplies and severely affecting local ecosystems. (credit: modification of work by USGS)

This loss of ice is leading to increases in the global sea level. On average, the sea is rising at a rate of 1.8 mm per year.

However, between 1993 and 2010 the rate of sea level increase ranged between 2.9 and 3.4 mm per year. A variety of factors affect the volume of water in the ocean, including the temperature of the water (the density of water is related to its temperature) and the amount of water found in rivers, lakes, glaciers, polar ice caps, and sea ice. As glaciers and polar ice caps melt, there is a significant contribution of liquid water that was previously frozen.

In addition to some abiotic conditions changing in response to climate change, many organisms are also being affected by the changes in temperature. Temperature and precipitation play key roles in determining the geographic distribution and phenology of plants and animals. (Phenology is the study of the effects of climatic conditions on the timing of periodic lifecycle events, such as flowering in plants or migration in birds.) Researchers have shown that 385 plant species in Great Britain are flowering 4.5 days sooner than was recorded earlier during the previous 40 years. In addition, insect-pollinated species were more likely to flower earlier than wind-pollinated species. The impact of changes in flowering date would be mitigated if the insect pollinators emerged earlier. This mismatched timing of plants and pollinators could result in injurious ecosystem effects because, for continued survival, insect-pollinated plants must flower when their pollinators are present.

### Think About It

What are possible short-term and long-term effects of natural and human-induced processes on global climate change and, consequently, ecosystems?

## KEY TERMS

**abiotic** nonliving components of the environment

**aboveground biomass** total mass of aboveground living plants per area

**abyssal zone** deepest part of the ocean at depths of 4000 m or greater

**algal bloom** rapid increase of algae in an aquatic system

**aphotic zone** part of the ocean where no light penetrates

**benthic realm** (also, benthic zone) part of the ocean that extends along the ocean bottom from the shoreline to the deepest parts of the ocean floor

**biogeography** study of the geographic distribution of living things and the abiotic factors that affect their distribution

**biome** ecological community of plants, animals, and other organisms that is adapted to a characteristic set of environmental conditions

**biotic** living components of the environment

**canopy** branches and foliage of trees that form a layer of overhead coverage in a forest

**channel** width of a river or stream from one bank to the other bank

**clathrates** frozen chunks of ice and methane found at the bottom of the ocean

**climate** long-term, predictable atmospheric conditions present in a specific area

**conspecifics** individuals that are members of the same species

**coral reef** ocean ridges formed by marine invertebrates living in warm, shallow waters within the photic zone

**cryptofauna** invertebrates found within the calcium carbonate substrate of coral reefs

**ecology** study of interaction between living things and their environment

**ecosystem services** human benefits and services provided by natural ecosystems

**emergent vegetation** wetland plants that are rooted in the soil but have portions of leaves, stems, and flowers extending above the water's surface

**endemic** species found only in a specific geographic area that is usually restricted in size

**estuary** biomes where a source of fresh water, such as a river, meets the ocean

**fall and spring turnover** seasonal process that recycles nutrients and oxygen from the bottom of a freshwater ecosystem to the top

**global climate change** altered global weather patterns, including a worldwide increase in temperature, due largely to rising levels of atmospheric carbon dioxide

**greenhouse effect** warming of Earth due to carbon dioxide and other greenhouse gases in the atmosphere

**greenhouse gases** atmospheric gases such as carbon dioxide and methane that absorb and emit radiation, thus trapping heat in Earth's atmosphere

**haze-effect cooling** effect of the gases and solids from a volcanic eruption on global climate

**heterospecifics** individuals that are members of different species

**intertidal zone** part of the ocean that is closest to land; parts extend above the water at low tide

**Milankovitch cycles** cyclic changes in the Earth's orbit that may affect climate

**neritic zone** part of the ocean that extends from low tide to the edge of the continental shelf

**net primary productivity** measurement of the energy accumulation within an ecosystem, calculated as the total amount of carbon fixed per year minus the amount that is oxidized during cellular respiration

**ocean upwelling** rising of deep ocean waters that occurs when prevailing winds blow along surface waters near a coastline

**oceanic zone** part of the ocean that begins offshore where the water measures 200 m deep or deeper

**pelagic realm** (also, pelagic zone) open ocean waters that are not close to the bottom or near the shore

**permafrost** perennially frozen portion of the Arctic tundra soil

**photic zone** portion of the ocean that light can penetrate

**planktivore** animal species that eats plankton

**predator** animal species that hunt and are carnivores or "flesh eaters"

**Sargassum** type of free-floating marine seaweed

**solar intensity** amount of solar power energy the sun emits in a given amount of time

**source water** point of origin of a river or stream

**thermocline** layer of water with a temperature that is significantly different from that of the surrounding layers

**weather** conditions of the atmosphere during a short period of time

## CHAPTER SUMMARY

### 35.1 The Scope of Ecology

Ecology is the study of the interactions of living things with their environment. Ecologists ask questions across four levels of biological organization—organismal, population, community, and ecosystem. At the organismal level, ecologists study individual organisms and how they interact with their environments. At the population and community levels, ecologists explore, respectively, how a population of organisms changes over time and the ways in which that population interacts with other species in the community. Ecologists studying an ecosystem examine the living species (the biotic components) of the ecosystem as well as the nonliving portions (the abiotic components), such as air, water, and soil, of the environment.

### 35.2 Biogeography

Biogeography is the study of the geographic distribution of living things and the abiotic factors that affect their distribution. Endemic species are species that are naturally found only in a specific geographic area. The distribution of living things is influenced by several environmental factors that are, in part, controlled by the latitude or elevation at which an organism is found. Ocean upwelling and spring and fall turnovers are important processes regulating the distribution of nutrients and other abiotic factors important in aquatic ecosystems. Energy sources, temperature, water, inorganic nutrients, and soil are factors limiting the distribution of living things in terrestrial systems. Net primary productivity is a measure of the amount of biomass produced by a biome.

### 35.3 Terrestrial Biomes

The Earth has terrestrial biomes and aquatic biomes. Aquatic biomes include both freshwater and marine environments. There are eight major terrestrial biomes: tropical wet forests, savannas, subtropical deserts, chaparral, temperate grasslands, temperate forests, boreal forests, and Arctic tundra. The same biome can occur in different geographic locations with similar climates. Temperature and precipitation, and variations in both, are key abiotic factors that shape the composition of animal and plant communities in terrestrial biomes. Some biomes, such as temperate grasslands and temperate forests, have distinct seasons, with cold weather and hot weather alternating throughout the year. In warm, moist

biomes, such as the tropical wet forest, net primary productivity is high, as warm temperatures, abundant water, and a year-round growing season fuel plant growth. Other biomes, such as deserts and tundra, have low primary productivity due to extreme temperatures and a shortage of available water.

### 35.4 Aquatic Biomes

Aquatic ecosystems include both saltwater and freshwater biomes. The abiotic factors important for the structuring of aquatic ecosystems can be different than those seen in terrestrial systems. Sunlight is a driving force behind the structure of forests and also is an important factor in bodies of water, especially those that are very deep, because of the role of photosynthesis in sustaining certain organisms. Density and temperature shape the structure of aquatic systems. Oceans may be thought of as consisting of different zones based on water depth and distance from the shoreline and light penetrance. Different kinds of organisms are adapted to the conditions found in each zone. Coral reefs are unique marine ecosystems that are home to a wide variety of species. Estuaries are found where rivers meet the ocean; their shallow waters provide nourishment and shelter for young crustaceans, mollusks, fishes, and many other species. Freshwater biomes include lakes, ponds, rivers, streams, and wetlands. Bogs are an interesting type of wetland characterized by standing water, lower pH, and a lack of nitrogen.

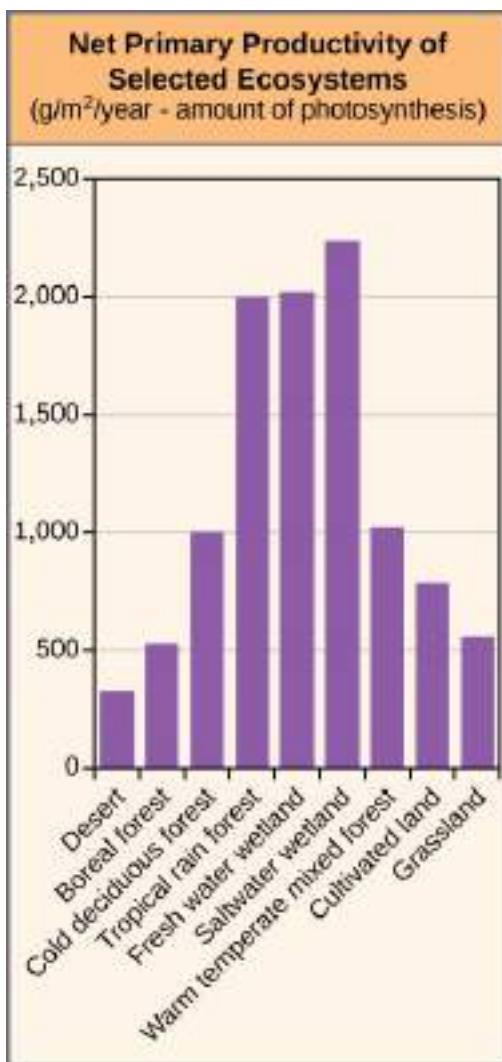

### 35.5 Climate and the Effects of Global Climate Change

The Earth has gone through periodic cycles of increases and decreases in temperature. During the past 2000 years, the Medieval Climate Anomaly was a warmer period, while the Little Ice Age was unusually cool. Both of these irregularities can be explained by natural causes of changes in climate, and, although the temperature changes were small, they had significant effects. Natural drivers of climate change include Milankovitch cycles, changes in solar activity, and volcanic eruptions. None of these factors, however, leads to rapid increases in global temperature or sustained increases in carbon dioxide. The burning of fossil fuels is an important source of greenhouse gases, which plays a major role in the greenhouse effect. Long ago, global warming resulted in the Permian extinction: a large-scale extinction event that is documented in the fossil record. Currently, modern-day climate change is associated with the increased melting of glaciers and polar ice sheets, resulting in a gradual increase in sea level. Plants and animals can also be affected by global climate change when the timing of seasonal events, such as flowering or pollination, is affected by global warming.

## REVIEW QUESTIONS

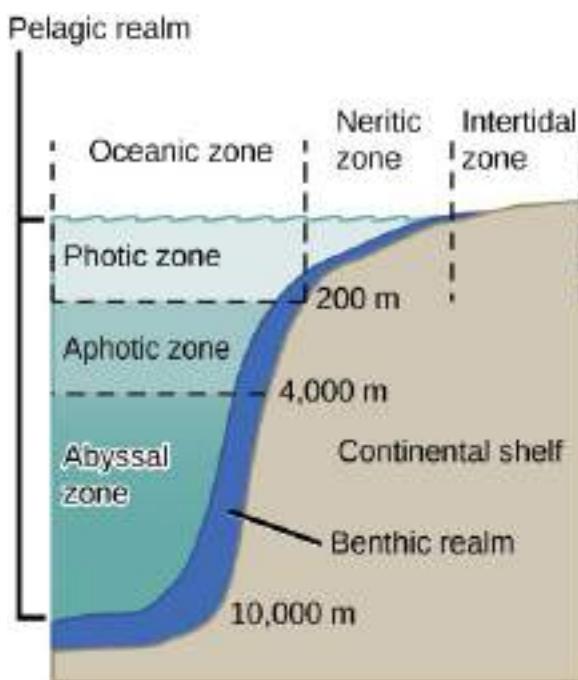

1. C, H, O and N are nutrients that are cycled through the Earth in different forms. Which of the following levels of ecology will include the study of nutrient cycling though the environment?
  - a. organismal ecology
  - b. population ecology
  - c. community ecology
  - d. ecosystem ecology
2. Which of the following are arranged from least inclusive to most inclusive?
  - a. population>ecosystem>community>biosphere
  - b. ecosystem < population < biosphere < community
  - c. biosphere < ecosystem < community < population
  - d. population < community < ecosystem < biosphere
3. An ecologist is studying the patterns on the wings of an endangered butterfly species that allow it to escape predators such as birds. This is an example of \_\_\_\_\_.
  - a. mimicry
  - b. organismal ecology
  - c. mutualism
  - d. community ecology
4. Each year, Lake Michigan beach visitors are warned of possible E.coli, which can cause illness. In order to understand how environmental conditions, both biotic and abiotic, affect E. coli risk, which type of individual should an infectious disease specialist collaborate with?
  - a. an ecosystem ecologist
  - b. a podiatrist
  - c. a community ecologist
  - d. a population ecologist
5. Some bacterial species can use nitrogen directly from the atmosphere. In this situation, the bacteria are a \_\_\_\_\_.
  - a. biotic factor
  - b. abiotic factor
  - c. predator
  - d. symbiotic partner
6. Photosynthetic organisms are important to most ecosystems because they \_\_\_\_\_.
  - a. mimicry
  - b. organismal ecology
  - c. mutualism
  - d. community ecology

- a. synthesize organic compounds they obtain from decaying heterotrophs.
- b. can use carbon dioxide and sunlight and synthesize their own food.
- c. use wind energy to synthesize organic compounds.
- d. synthesize inorganic compounds from organic compounds.
7. The study of population ecology focuses on \_\_\_\_.
- The number of individuals of one species in an area and how and why that number changes over time.
  - The processes driving interactions within and among different species within an area.
  - The adaptations that enable individuals to live in specific habitats.
  - Plants and animals living in an enclosed area
8. The study of the effect of abiotic factors such as rain and temperature on the distribution of living organisms is known as \_\_\_\_.
- community ecology
  - biogeography
  - ecosystem
  - geography
9. Many species of pine trees are found in different geographical locations in North America and Canada. This is because \_\_\_\_.
- they were not separated geographically over millions of years and did not evolve to be different species.
  - plant breeders carried seeds to different areas.
  - pollen from pollen tree was able to travel far.
  - pine was present widely and in some areas they dried out.
10. An ecologist hiking up a mountain may notice different biomes along the way due to changes in all of the following except \_\_\_\_.
- elevation
  - rainfall
  - latitude
  - temperature
11. Temperate forests have plants of varying sizes. Understory plants in a temperate forest have adaptations to capture limited \_\_\_\_.
- a. water
- b. nutrients
- c. heat
- d. sunlight
12. In which of the following bodies of water does temperature stratification not take place?
- estuaries
  - lakes
  - seas
  - oceans
13. Plants living in deserts have adaptations such as hair on leaves and a thick cuticle. What purpose do these adaptations serve?
- to conserve water
  - to prevent exposure to sunlight
  - to increase oxygen intake
  - to decrease carbon dioxide intake
14. Which of the following biomes would have maximum net primary production?
- deciduous forests
  - deserts
  - arctic tundra
  - savannas
15. When the Net Primary Productivity was measured in the presented graph, what was included in those measurements?

16. Biogeography is the study of the geographic distribution of living things and the \_\_\_\_\_ that affect their distribution.
- Abiotic factors
  - Biotic factors
  - Biomes
  - Conspecifics
17. In which of the biomes are plants unable to grow because the soil is frozen most of the year?
- arctic tundra
  - boreal forests
  - grasslands
  - chapparals

18. In grasslands, forest fires are a common occurrence. Which of the following statements regarding grasslands is true?
- They have the ability to withstand fires.
  - They have a well-developed root system, which allows them to regrow after a fire.
  - Grasses are tall and only their top portions are destroyed.
  - Trees shield some of the grass thus protecting it from fire.
19. Savannas are grasslands with scattered trees. Which statement is correct about savannas?
- They receive abundant rainfall.
  - The temperatures are cold throughout the year.
  - They have relatively long dry seasons.
  - Savannas are dominated by fluctuations in temperature.
20. The boreal forest, also known as taiga or coniferous forest, is found south of the Arctic Circle and across most of Canada, Alaska, Russia, and northern Europe. What are the characteristics of the boreal forest?
- high temperature
  - deciduous trees
  - high humidity
  - acidic soil
21. The amount of sunlight and rainfall affects the growing season of plants in different biomes. Which of the following biomes is characterized by short growing seasons?
- savanna
  - temperate grasslands
  - arctic tundra
  - tropical wet forest
22. The figure shows different zones present in the ocean. Which of the following statements about marine biomes is true?

- 23.** Corals have a mutualistic relationship with photosynthetic algae in the photic zones of water. What purpose does this serve?
- Corals are able to derive their nutrition from the algae and thus survive in the nutritionally poor water.
  - Corals are able to accumulate calcium carbonate from the algae.
  - They can form coral reefs because of this association.
  - The corals provide protection to the algae.
- 24.** Which of the following abiotic factors is most important for sustaining life in marine biomes?
- wind
  - soil
  - salt
  - warmth
- 25.** There are several different marine zones. In which zone are organisms exposed to air and sunlight at low tide and are underwater most of the time, especially during high tide?
- intertidal zone
  - neritic
  - oceanic
  - abyssal
- 26.** Which of the following photosynthetic organisms are more likely to grow in a lake as opposed to a river?
- fungi
  - phytoplankton
  - moss
  - lichens
- 27.** Water flow can vary in wetlands. Freshwater marshes and swamps are characterized by \_\_\_\_\_.  
  - dry soil
  - rapid water flow
  - slow water flow
  - irregular water flow
- 28.** Water bodies can differ in the amount of salt present. Which of the following is a characteristic of an estuary?
- a continuous body of water with high salinity
  - an area where the salinity varies
  - a body of water with low salinity
  - a body of water with low salt entering land
- 29.** The earth's geological past has witnessed many important events. Which of the following periods was associated with global warming?
- Permian period
  - Cambrian period
  - 2nd and 3rd century BC
  - 20th century
- 30.** One of the indirect consequences of global warming has been \_\_\_\_\_.  
  - loss of biodiversity
  - increase in temperature
  - change in water quality
  - increase in temperature tolerance of plants
- 31.** Which one of the following fuels was used extensively during the Industrial Revolution, leading to increases in levels of carbon dioxide?
- coal
  - petroleum
  - natural gas
  - solar energy
- 32.** Global warming is due to many factors. Which of the following is known to change with CO<sub>2</sub> concentration?

- a. solar intensity
- b. wind intensity
- c. temperature
- d. humidity

33. All of the following are natural factors have led to slow increases in global temperatures except \_\_\_\_.

- a. volcanic eruptions
- b. change in solar intensity
- c. earthquakes
- d. changes in the earth's orbit

34. Global temperatures have been steadily increasing since the Industrial Revolution largely as a result of \_\_\_\_.

- a. agricultural production
- b. burning of fossil fuels
- c. increase in movement of people
- d. use of pesticides

35. Which of the following gases is not considered a significant contributor to global warming?

- a. carbon dioxide
- b. methane
- c. nitric oxide
- d. oxygen

36. Carbon dioxide, methane, and nitrous oxide are considered greenhouse gases because \_\_\_\_.

- a. They trap solar radiation released from the sun as it reaches the Earth's surface, similar to the glass in a greenhouse.
- b. They are found mostly in green houses.
- c. These gases are essential for plant growth in a green house.
- d. They trap solar radiation, which is converted into thermal radiation on the Earth's surface of which some is reradiated back into the atmosphere.

37. The Medieval Climate Anomaly occurred between 900 and 1300 AD. Temperatures during this time were between 0.10 and 0.20 higher. This allowed \_\_\_\_.

- a. the Vikings to colonize Greenland
- b. large amounts of new technologies to be invented
- c. advances in agriculture
- d. harsh winters

## CRITICAL THINKING QUESTIONS

38. Define and describe community ecology. Give an example.

- a. It is the study of the number of individuals of one species in an area as well as how and why the number changes over time. An example would be counting the number of individuals of the Karner blue butterfly, a federally endangered species whose population density is highly influenced by the abundance of wild lupine.
- b. It is the study of the processes and consequences of interactions within and among different species within an area. An example would be the work of scientists who work in a marsh studying the various interactions of several populations of birds, crabs, and grasses without studying the water or air quality.
- c. It is the study of the physiological, morphological, and behavioral adaptations that enable individuals to live in specific habitats. An example would be the work of scientists who work in a marsh studying the various interactions of several populations of birds, crabs, and grasses without studying the water or air quality.
- d. It is the study of the processes and consequences of interactions within and among different species within an area. An example would be counting the number of individuals of the Karner blue butterfly, a federally endangered species whose population density is highly influenced by the abundance of wild lupine.

**39.** Ecologists often collaborate with other researchers interested in ecological questions. Describe the levels of ecology that would be easier for collaboration because of the similarities of questions asked. What levels of ecology might be more difficult for collaboration?

- a. It is easier to study community and ecosystem ecology as the effect of biotic and abiotic factors can be studied in a community or ecosystem more easily. Organismal and population ecology might be more difficult for collaboration.
- b. It is easier to study organismal and population ecology as the effect of biotic and abiotic factors can be studied in an organism or population more easily. Community and ecosystem ecology might be more difficult for collaboration.
- c. It is easier to study community and population ecology as the effect of biotic and abiotic factors can be studied in easily in a community or population more easily. Organismal and ecosystem ecology might be more difficult for collaboration.
- d. It is easier to study organismal and ecosystem ecology as the effect of biotic and abiotic factors can be studied in an organism or ecosystem more easily. Community and population ecology might be more difficult for collaboration.

**40.** How do organisms return nutrients and water to the environment?

- a. By cycling between the abiotic and biotic environment.
- b. By cycling between evaporation and transpiration.
- c. By cycling between the flora and fauna of the Earth.
- d. By cycling between temperature and moisture.

**41.** Define and give an example of organismal, population and community ecology.

- a. Organismal ecology includes the study of the number of individuals in an area as well as how and why population size changes over time, such as a study of the drop in antelope population. Population ecology includes the study of adaptations that enable individuals to live in specific habitats, such as a study of the use of opposable thumbs. Community ecology includes the study of the processes and consequences of interactions within and among different species in an area, such as a study of interactions between wolves and deer.
- b. Organismal ecology includes the study of the processes and consequences of interactions within and among different species in an area, such as a study of the interactions between wolves and deer. Population ecology includes the study of the number of individuals in an area as well as how and why population size changes over time, such as a study of the drop in antelope population. Community ecology includes the study of adaptations that enable individuals to live in specific habitats, such as a study of the use of opposable thumbs.
- c. Organismal ecology includes the study of adaptations that enable individuals to live in specific habitats, such as a study of the use of opposable thumbs. Population ecology includes the study of the number of individuals in an area as well as how and why population size changes over time, such as a study of the drop in antelope population. Community ecology includes studies of the processes and consequences of interactions within and among different species in an area, such as a study of the interactions between wolves and deer.
- d. Organismal ecology includes studies of the adaptations that enable individuals to live in specific habitats, such as a study of the use of opposable thumbs. Population ecology includes studies of the processes and consequences of interactions within and among different species in an area, such as a study of the interactions between wolves and deer. Community ecology includes studies of the number of individuals in an area as well as how and why population size changes over time, such as a study of the drop in antelope population.
- 42.** Many endemic species are found in areas that are geographically isolated. Suggest a plausible scientific explanation why this is so.
- a. Geographically isolated areas have provided high temperature conditions for certain species to evolve. Over time, these species retained their unique characteristics because they remained separated from other species.
- b. Geographically isolated areas have provided a unique environment for certain species to evolve. Over time, these species retained their unique characteristics because they remained separated from other species.
- c. Certain species are introduced into some geographically isolated areas, which provide them unique environments. Over time, these species retained their unique characteristics because they remained separated from other species.
- d. A unique environment is provided for certain species to evolve in vitro and these species are introduced into geographically isolated areas. Over time, these species retained their unique characteristics because they remained separated from other species.
- 43.** The American white pelican migrates from North America to Central America in the winter months. Give three reasons why these birds follow an annual migration pattern.
- a. The American white pelican follows an annual migration pattern in search of suitable mates, warmer climates, and suitable habitat. Warmer climates help them in maintaining a constant body temperature.
- b. The American white pelican follows an annual migration pattern in search of food, salt water, and cooler climates. Cooler climates help these birds in reproduction.
- c. The American white pelican follows an annual migration pattern in search of food, warmer climates, and suitable habitat. Warmer climates help them in maintaining a constant body temperature.
- d. The American white pelican follows an annual migration pattern in search of warmer climates only. Warmer climates help them in maintaining a constant body temperature.
- 44.** Why is it essential for organisms to maintain a constant body temperature? Describe adaptations that help the organisms cope with changes in environmental temperature.

- a. The rate of metabolic processes increases at very high or low temperatures. So, organisms have to maintain a constant body temperature. This can be achieved only by migration to avoid seasonal temperature changes.
- b. Enzymes that carry out metabolic processes are denatured at very high temperatures. So, organisms have to maintain a constant body temperature. This can be achieved by hibernation, aestivation, or migration.
- c. The rate of metabolic processes increases at very high or low temperatures. So, organisms have to maintain a constant body temperature. This can be achieved by hibernation, aestivation, or migration.
- d. Enzymes that carry out metabolic processes are denatured at very high temperatures. So, organisms have to maintain a constant body temperature. This can be achieved only by migration to avoid seasonal temperature changes.
- 45.** The extremely low precipitation of subtropical desert biomes might lead one to expect fire to be a major disturbance factor. However, fire is more common in the temperate grassland biome than in the sub tropic desert biome. Why is this?
- a. Due to higher net primary productivity, biomass in deserts is significantly more than in temperate grassland biomes. However, it is easier for fire to spread in grasslands as they are found in abundance.
- b. Due to lower net primary productivity, biomass in deserts is significantly less than in temperate grassland biomes. It is easier for fire to spread in grasslands as they are found in abundance.
- c. Due to lower net primary productivity, biomass in deserts is significantly less than in temperate grassland biomes. It is easier for fire to spread in grasslands as they have very low precipitation and high temperatures.
- d. Due to higher net primary productivity, biomass in deserts is significantly more than in temperate grassland biomes. However, it is easier for fire to spread in grasslands as they have very low precipitation and high temperatures.
- 46.** What are endemic species? Give an example and explain how endemic species differ from generalist species.
- a. Endemic species are found naturally in specific geographic areas that are usually restricted in size. For example, the raccoon is found only in Australia. Generalist species are found in a wide range of geographical locations. For example, the koala is native to most of North and Central America.
- b. Endemic species are those which are likely to be extinct. For example, the koala (a marsupial) is found only in Australia. Generalist species are found in a wide range of geographical locations. For example, the raccoon is native to most of North and Central America.
- c. Endemic species are found in a wide range of geographical locations. For example, the koala (a marsupial) is found only in Australia. Generalist species are found naturally in specific geographic areas that are usually restricted in size. For example, the raccoon is native to most of North and Central America.
- d. Endemic species are found naturally in specific geographic areas that are usually restricted in size. For example, the koala (a marsupial) is found only in Australia. Generalist species are found in a wide range of geographical locations. For example, the raccoon is native to most of North and Central America.
- 47.** Deserts and subtropical deserts experience low precipitation and extremes in temperature. For a plant to survive and reproduce, what adaptations should it have? Why?
- a. To survive, they need prop roots, reduced foliage and fleshy leaves with sunken stomata to reduce transpiration. Also, they should have seeds that can remain dormant over long periods.
- b. To survive, they need deep roots, reduced foliage and fleshy leaves with sunken stomata to reduce transpiration. Also, they should have seeds that can remain dormant over long periods.
- c. To survive, they need deep roots, reduced foliage and fleshy leaves with sunken stomata to reduce transpiration. Also, these plants need to grow in clumps.
- d. To survive, they need deep roots, increased foliage, and fleshy leaves with sunken stomata to reduce transpiration. Also, the plants need seeds that can remain dormant over long periods.
- 48.** In what ways are the subtropical desert and the arctic tundra similar?

- a. Both are characterized by animals, which are adapted to burrowing.
- b. Both are characterized by plants, which prefer to grow in clumps.
- c. Both are characterized by low water availability and, as a result, low net primary productivity.
- d. Both are characterized by plants, which are mostly perennials.

**49.** Describe the chaparral biome. How does it differ from subtropical deserts?

- a. Shrubs dominate chaparral vegetation and are well adapted to the periodic fires in the area. Ashes left behind after fires are rich in nutrients, which promote regrowth. Subtropical deserts are characterized by their high precipitation and water-retaining plants.
- b. Shrubs dominate chaparral vegetation and are well adapted to the periodic fires in the area. Ashes left behind after fires are rich in nutrients, which promote regrowth. Subtropical deserts are characterized by their low precipitation and water-retaining plants.
- c. Lichens dominate chaparral vegetation and are well adapted to the periodic fires in the area. Ashes left behind after fires are rich in nutrients, which promote regrowth. Subtropical deserts are characterized by their low precipitation and water-retaining plants.
- d. Shrubs dominate chaparral vegetation but are not well adapted to the periodic fires in the area. Ashes left behind after fires are rich in nutrients, which promote regrowth. Subtropical deserts are characterized by their low precipitation and water-retaining plants.

**50.** What happens to aquatic life in deep lakes when water freezes during the winter months?

- a. During winters, layer of ice falls on water surface as it is less dense than water. Water is densest at 7° C and retains its liquid form below the water surface. The aquatic life can exist in liquid water.
- b. During winters, the aquatic life exists in liquid water, which is present below the surface layer, by consuming more resources so they can survive during the harsh winter season.
- c. During winters, a layer of ice forms on the water surface, as ice is less dense than water. Water is densest at 4°C and retains its liquid form below the water surface, where the ice layer is. In liquid water, the aquatic life can survive using the resources available.
- d. During winters, ice forms only on the surface and a few meters below the surface of water. Water is densest at 4°C and retains its liquid form below the water surface, where the ice layer is. In liquid water, the aquatic life can exist using the resources available.

**51.** Explain the challenges facing organisms living in the intertidal zone and their adaptations to meet these challenges.

- a. They are subject to constant exposure to air, sunlight, periods of dryness, and pounding waves. For this reason, some species have an exoskeleton.
- b. They are subject to periodic exposures to air, sunlight, periods of dryness, and pounding waves. For this reason, some species have an exoskeleton.
- c. They are subject to periodic exposures to air, sunlight, periods of dryness, and pounding waves. For this reason, all species have an exoskeleton.
- d. They are subject to periodic exposures to air, sunlight, periods of dryness, and pounding waves. For this reason, most species have an endoskeleton.

**52.** If algae grows out of proportion as seen during algal blooms, how does it affect the ecosystem?

- a. Photosynthetic organisms will not be able to grow. The animals and birds that live on those organisms will be affected. As the algae die, oxygen will be depleted, affecting fish and other aquatic animals. The pH of water will change, affecting metabolic processes as well.
  - b. Non-photosynthetic organisms will not be able to grow due to lack of light. The photosynthetic organisms that require them to live will be affected. As the algae die, oxygen will be depleted, affecting fish and other aquatic animals. The pH of water will change, affecting metabolic processes as well.
  - c. Photosynthetic organisms will not be able to grow. The animals and birds that live on those organisms will be affected. As the algae die, carbon dioxide will be depleted, affecting fish and other aquatic animals. The pH of water will change, affecting metabolic processes as well.
  - d. Non-photosynthetic organisms will not be able to grow. The animals and birds that live on those organisms will be affected. As the algae die, carbon dioxide will be depleted, affecting fish and other aquatic animals. The pH of water will change, affecting metabolic processes as well.
53. What are some abiotic factors that affect freshwater biomes? Explain.
- a. Salinity and sunlight are both abiotic factors that influence life in freshwater biomes. As organisms living in freshwater biomes require high salt density for survival, its depletion would kill the organisms. Many organisms that serve as food for others are photosynthetic and would die if algae blooms obscured the light. Their decomposition as well as the depletion of oxygen by algae would cause organisms that require oxygen to die out as well.
  - b. Salinity and sunlight are both abiotic factors that influence life in freshwater biomes. As organisms living in freshwater biomes cannot tolerate high salt levels, these organisms would not survive if it increased. Many organisms that serve as food for others are photosynthetic would die if algal blooms obscured the light. Their decomposition and the depletion of carbon dioxide by algae would cause organisms that require carbon dioxide to die out as well.
  - c. Salinity and sunlight are both abiotic factors that influence life in freshwater biomes. As organisms living in freshwater biomes cannot tolerate high salt levels, these organisms would not survive if it were to increase significantly. Many organisms that serve as food for others are photosynthetic and would die if algal blooms obscure light. Their decomposition and depletion of oxygen by algae would cause organisms that require oxygen to die out as well.
  - d. Salinity and temperature are both abiotic factors that influence life in freshwater biomes. As organisms living in freshwater biomes cannot tolerate high salt concentrations, those organisms would not survive if salt concentrations increased significantly. Many organisms that serve as food for others are photosynthetic and would die if algal blooms obscured the light. Their decomposition and the depletion of oxygen by algae would cause organisms that require oxygen to die out as well.
54. Is it possible to reverse global warming? What measures may help in reducing global climate change?

- a. It is possible to reverse global warming by reducing the usage of fossil fuels, using alternative fuels, using alternatives to CFC's and using natural sources of energy.
- b. It is not possible to reverse global warming, as major climate changes have already been occurred and settled in the environment. Reducing fossil fuel usage, using natural sources of energy and alternative fuels may slow down global climate change.
- c. It is not possible to reverse global warming, as we are already witnessing changes in the environment, plants and animal behavior. Reducing fossil fuel usage and using natural sources of energy may slow down global climate change.
- d. It is possible to reverse global warming by working on new technologies that will help in preventing temperature changes worldwide. Using wind power and high efficiency natural gas generation will help in achieving this goal.

55. As global temperatures change, many flowering plants are flowering earlier. What change would most likely occur if the insect pollinators are not around at the same time?

- a. Insects will be deprived of their nectar, leading to decrease in numbers; but flowering plants will not be affected, as other animals will pollinate them.
- b. Flowering plants will not be pollinated resulting in their less population; but insects will not be affected, as insects will feed on other organisms.
- c. Neither plants nor pollinators will be affected, as new or different species of insects are going to pollinate the flowering plants.
- d. Both plant and pollinator numbers would decrease, as insects will be deprived of nectar and plants will not be pollinated.

56. If scientists had to predict the rise in Earth's temperature in the next one hundred years, what would they take into consideration?

- a. Scientists can predict the change in earth's temperature only by analyzing previous and current data such as dimensions and locations of glaciers as well as the water levels in lakes, rivers, and oceans.
- b. Scientists could predict rise in temperature by analyzing previous and current data like dimensions and locations of glaciers, water levels in lakes, rivers and oceans and by counting and examining number of annual rings in trees.
- c. Scientists could predict rise in earth's temperature by measuring the greenhouse gases present in the current atmosphere. Counting and examining the number of annual rings in trees would also point to the climactic changes over the years.
- d. Scientists can predict the change in earth's atmosphere by counting and analyzing the number of annual rings in trees. Also, analyzing ice cores for over a year would predict the rise in Earth's temperature in the next one hundred years.

57. Many people cannot imagine a world without fossil fuels, but fossil fuels are finite resources and will eventually run out. This is why drilling had begun in Arctic in an effort to find a new source of fossil fuels, though it is currently stopped. What are the dangers of drilling in the Arctic? What are the alternatives?

- a. Drilling as well as melting of ice in the Arctic results in the release of large amounts of methane, accelerating global warming. Investing in clean energy like wind, water, and solar power, which do not release harmful gases, could be the alternative.
- b. Drilling as well as melting of ice in the Arctic results in the release of large amounts of carbon monoxide, accelerating global warming. Investing in clean energy like wind, water, and solar power, which do not release harmful gases, could be the alternative.
- c. Drilling as well as melting of ice in the Arctic results in the release of large amounts of carbon monoxide, which is lethal and can cause death. Investing in clean energy like wind, water, and solar power, which do not release harmful gases, could be the alternative.
- d. Drilling as well as melting of ice in the Arctic results in the release of large amounts of methane, accelerating global warming. Investing in mining of earth minerals and metal ores could be the alternative.

## TEST PREP FOR AP® COURSES

**58.** The Karner blue butterfly has been declared an endangered species. It is dependent on wild lupine for larval development. The butterfly species, which was found abundantly in Indiana Dunes National Park, is now found further North in Wisconsin and Michigan. Wild lupine has been destroyed in areas where it grew abundantly because of development and construction in the open grasslands where it prefers to grow. Which of the following biotic factors are present in the community?

- a. Karner blue butterfly
- b. Karner blue butterfly and wild lupine
- c. Karner blue butterfly, wild lupine, and fire
- d. Karner blue butterfly, wild lupine, and grasslands

**59.** In a temperate grassland system area of North America, vegetation has been destroyed by fire. What will happen to the net primary productivity and the local ecosystem when rains return in the next season?

- a. The grasses will grow back, but the herbivores that lived there will not return, as they would have found new land to live on. Therefore, the net primary productivity would decrease.
- b. The grasses will not grow back, therefore the herbivores that lived there will not return. Thus, the net primary productivity would decrease.
- c. The grasses will grow back and the herbivores that lived there will return. The net primary productivity should also be similar to the previous season.
- d. The grasses will grow back and the herbivores that lived there will return. The net primary productivity would be less than the previous season.

**60.** The Karner blue butterfly larva secretes a carbohydrate, which is a source of energy for ants. In turn, ants tend to the larva, increasing its likelihood to grow into an adult butterfly. This is an example of \_\_\_\_.

- a. predation
- b. competition
- c. mutualism
- d. parasitism

**61.** A lake in the Midwest witnesses a sudden increase in the algae population (algae bloom) that covers the lake. The factors that affect net primary productivity are \_\_\_\_.

- a. Light and nutrient availability
- b. predation by primary consumers
- c. pollution
- d. carbon dioxide

**62.** Paleontologists have discovered bodies of humans and animals in bogs that have been there for hundreds of years in a perfectly preserved state. Explain the reason for this.

- a. Bogs have high oxygen content and organic acids, which lowers the pH. Low pH and high oxygen content prevents oxidation thus, slowing down decomposition.
- b. Bogs have low oxygen content and organic acids, which increases the pH. High pH and low oxygen content prevents oxidation thus, slowing down decomposition.
- c. Bogs have low oxygen content and organic acids, which lowers the pH. Low pH and low oxygen content prevent oxidation, thus slowing down decomposition.
- d. Bogs have low oxygen content and organic acids, which lowers the pH. Low pH and low oxygen content prevents reduction, thus slowing down decomposition.

**63.** You are asked to estimate the nutrient content of a lake and its possible effect on net primary productivity. What data will you collect to determine the effect?

- a. Sample water from different parts of the lake and determine nutrient composition
- b. Sample the carbon content of the phytoplankton growing
- c. Take sample of lake water and artificially enrich it, then see the effect of the enrichment on phytoplankton growth compared with growth in unenriched lake water
- d. Wait for spring turnover to check for nutrients found in the ocean floor

**64.** The population of a certain species of deer has been reduced drastically because of indiscriminate hunting. How will you determine its impact on the local ecosystem?

- a. To determine the effect of indiscriminate hunting on local ecosystem, environmental conditions should be determined. If a drastic change in environmental conditions is observed then, indiscriminate hunting of deer should be discouraged.
- b. The number of predators, their effect on plants they feed on, availability of nutrients in soil, and number of pests should be determined. If there is a drastic change in numbers, then indiscriminate hunting of deer should be discouraged.
- c. Determining the number of predators alone is sufficient to determine the impact of indiscriminate hunting on local ecosystem. If there is a drastic change in numbers, then indiscriminate hunting of deer should be discouraged.
- d. Determination of the availability of nutrients in soil helps in determining the impact of indiscriminate hunting on local ecosystem. If there is a drastic change in the availability, then indiscriminate hunting of deer should be discouraged.

**65.** In a forest fire, many oak trees were destroyed. After the fire, numerous taller trees replaced the oak trees. What is the best explanation of this event?

- a. The tall trees grow faster and create a canopy, which did not allow oak trees to grow.
- b. The burning of the trees changed the pH of the soil, which did not allow oak to grow.
- c. Roots of shrubs and trees proliferate, taking over the place of the oak trees.
- d. Oak trees succumb to pests, thus other pest resistant trees are able to proliferate.

**66.** What are possible consequences if there is a big oil spill in the middle of the ocean? How will it affect the biodiversity and the net primary productivity? What are some strategies to clean up this oil spill?

- a. Oil spills increase the amount of light and oxygen entering the ocean. The phytoplanktons may perish. Presence of oil would limit mobility of marine animals and may result in death. Some chemicals and bioremediation can help oil clean up.
- b. Oil spills increase the amount of light and oxygen entering the ocean. The phytoplanktons may increase. The mobility of marine animals increases. Biodiversity and, therefore, net primary productivity increases. Some chemicals and bioremediation can help oil clean up.
- c. Oil spills cover the surface of the ocean, reducing the amount of light entering the ocean. The marine organisms that can survive independent of light will not be affected. Some chemicals and bioremediation can help oil clean up.
- d. Oil spills cover the surface of the ocean, reducing the amount of light and oxygen entering the ocean. The phytoplankton may perish. Presence of oil would limit mobility of marine animals and may result in death. Some chemicals and bioremediation can help oil clean up.

**67.** Global climate change has led to butterflies emerging earlier and amphibians mating earlier in the United Kingdom. What impact is it most likely to have on their populations in the next few years?

- a. There will be no impact on butterfly and amphibian population.
- b. Their numbers will definitely decline with rising temperatures.
- c. Their numbers will decline as their plant hosts of butterflies may not flower earlier and young amphibians may not be viable as there might be a lack of water.
- d. It is hard to predict what will happen to their populations as there are no similar studies.

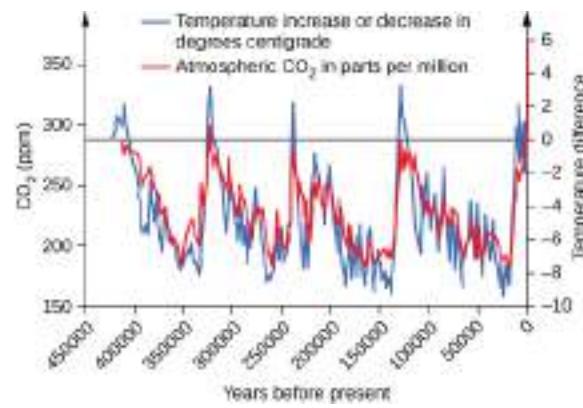

**68.** What are possible short-term and long-term effects of natural and human-induced processes on global climate change and, consequently, ecosystems?

- a. Short term changes include melting of glaciers, rise in levels of water bodies which may cover islands close to sea level, destroying the local ecosystem and animals, and so on. Long-term changes experienced could include changes in seasonal patterns, unseasonal rainfall, and changes in the life cycle of insects.
- b. Short term changes include changes in seasonal patterns, unseasonal rainfall, changes in the life cycle of insects and animals, and so on. Long-term changes could be change in flowering times of flowers, and the rise in levels of water bodies, which may cover islands close to sea level, destroying the local ecosystem.
- c. Short-term changes include changes in seasonal patterns, unseasonal rainfall, changes in the life cycle of insects and animals, and so on. Long-term changes could be melting of glaciers, and a rise in levels of water bodies which may cover islands close to sea level, destroying the local ecosystem.
- d. Short term changes include melting of glaciers, unseasonal rainfall, changes in the life cycle of insects and animals, etc. Long-term changes could be rise in levels of water bodies which may cover islands close to sea level, destroying the local ecosystem.

## SCIENCE PRACTICE CHALLENGE QUESTIONS

**69.** Twenty targets for the protection of biodiversity by 2020 were established by the 2010 Convention on Biological Diversity. Midway to the target date it is widely agreed that the goals will not be met. The *2016 Living Planet Report* from the World Wildlife Federation claims global populations of animals fell by 58 percent between 1970 and 2012 and extrapolates the loss by 2020 to 67%. E.O. Wilson's estimate of the current extinction rate is three species per hour. Geologic periods are defined by mass extinctions. The proposed name for the current geological period is the Anthropocene (Waters et al., *Science*, 2016).

During the current period of mass extinction, human activities are driving loss of habitat and climate change. Climate change during the last 500,000 years is a direct consequence of rising atmospheric CO<sub>2</sub> levels, as the graph shows. The relative abundance of O<sup>16</sup> and O<sup>18</sup> isotopes can be used to infer temperature because as temperature increases the lower mass isotope is enriched in the atmosphere (objects with a smaller mass have a higher velocity at equal molecular kinetic energy that is proportional to temperature).

**Figure 35.31**

The role of humans in the last great extinction, the Holocene Extinction, during which the megafauna such as the wooly mammoth, the wooly rhinoceros and the giant deer disappeared, has long been debated. Did we hunt these creatures to extinction? By examining all available DNA evidence, Cooper et al. (*Science*, 349, 2015) have compared time extinction intervals with these oscillations of climate as shown in the table.

| Animal          | Label | Loc-<br>ation    | Begin<br>extinct<br>event<br>(TYA) | End<br>extinct<br>event<br>(TYA) |
|-----------------|-------|------------------|------------------------------------|----------------------------------|
| Bear            | a     | Ber-<br>ingia    | 24                                 | 21                               |
| Bison           | b     | Europe           | 35                                 | 32                               |
| Rhino-<br>ceros | c     | Britain          | 36                                 | 32                               |
| Rhino-<br>ceros | d     | Russia           | 14                                 | 13                               |
| Horse           | e     | North<br>America | 15                                 | 13                               |
| Horse           | f     | Ber-<br>ingia    | 43                                 | 38                               |
| Mast-<br>odon   | g     | North<br>America | 12                                 | 11                               |
| Mam-<br>moth    | h     | Europe           | 13                                 | 12                               |
| Mam-<br>moth    | i     | Eurasia          | 11                                 | 10                               |
| Musk<br>Ox      | j     | Eurasia          | 48                                 | 44                               |
| Deer            | k     | Europe           | 13                                 | 12                               |
| Cave<br>Lion    | l     | Ber-<br>ingia    | 14                                 | 12                               |
| Cave<br>Bear    | m     | Europe           | 29                                 | 27                               |

Table 35.1 TYA = thousand years ago

Additionally, the data shown in the graph below are obtained from ice cores. The deeper the sample, the older the sample. The percent departure from the current O<sup>18</sup> percentage that is graphed above is a measure of temperature relative to the present temperature. The higher the isotope concentration, the higher the average temperature of the ocean.

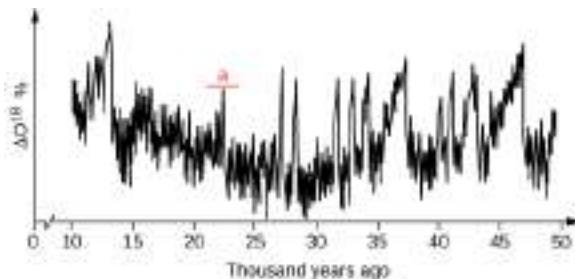

Figure 35.32

- A. **Refine** the graph by adding the interval of time of extinction with a label drawn from the table as shown by "a".
- B. **Analyze** these data in terms of the clustering of extinction events.
- C. Based on your analysis, **explain** how ecosystems have changed during the last 40,000 years, **changed** and **identify** the factor that caused these changes.
- D. Based on the correlation between Earth's temperature and the concentration of CO<sub>2</sub> in the atmosphere, **predict** what will happen to animal populations in the future.

# 36 | POPULATION AND COMMUNITY ECOLOGY

**Figure 36.1** Asian carp jump out of the water in response to electrofishing. The Asian carp in the inset photograph were harvested from the Little Calumet River in Illinois in May, 2010, using rotenone, a toxin often used as an insecticide, in an effort to learn more about the population of the species. (credit main image: modification of work by USGS; credit inset: modification of work by Lt. David French, USCG)

## Chapter Outline

- 36.1: Population Demography**
- 36.2: Life Histories and Natural Selection**
- 36.3: Environmental Limits to Population Growth**
- 36.4: Population Dynamics and Regulation**
- 36.5: Human Population Growth**
- 36.6: Community Ecology**
- 36.7: Behavioral Biology: Proximate and Ultimate Causes of Behavior**

## Introduction

Imagine sailing down a river in a small motorboat on a weekend afternoon; the water is smooth and you are enjoying the warm sunshine and cool breeze when suddenly you are hit in the head by a 20-pound silver carp. This is a risk now on many rivers and canal systems in Illinois and Missouri because of the presence of Asian carp.

This fish—actually a group of species including the silver, black, grass, and big head carp—has been farmed and eaten in China for over 1000 years. It is one of the most important aquaculture food resources worldwide. In the United States, however, Asian carp is considered a dangerous invasive species that disrupts community structure and composition to the point of threatening native species.

The Asian carp is now threatening to invade the Great Lakes. You can read more about this invasion [here](http://openstaxcollege.org/l/32asiancarp) (<http://openstaxcollege.org/l/32asiancarp>) .

## 36.1 | Population Demography

In this section, you will explore the following questions:

- How do ecologists measure population size and density?
- What are three different patterns of population distribution?
- How can life tables be used to calculate mortality rates?
- What are the three types of survivorship curves and how do they relate to specific populations?

### Connection for AP® Courses

By using mathematics, ecologists can study how interactions among living organisms and with their environment affect the distribution, abundance, density, and life strategies of species. A population consists of individuals of the same species living within a specific area. Populations fluctuate based on both biotic and abiotic factors. When studying a population, characteristics of that population are quantified and their change is monitored. This statistical study of these changes, **demography**, investigates how populations respond to these fluctuations. A shift in populations can affect community structure and the ecosystem as a whole.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 and Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

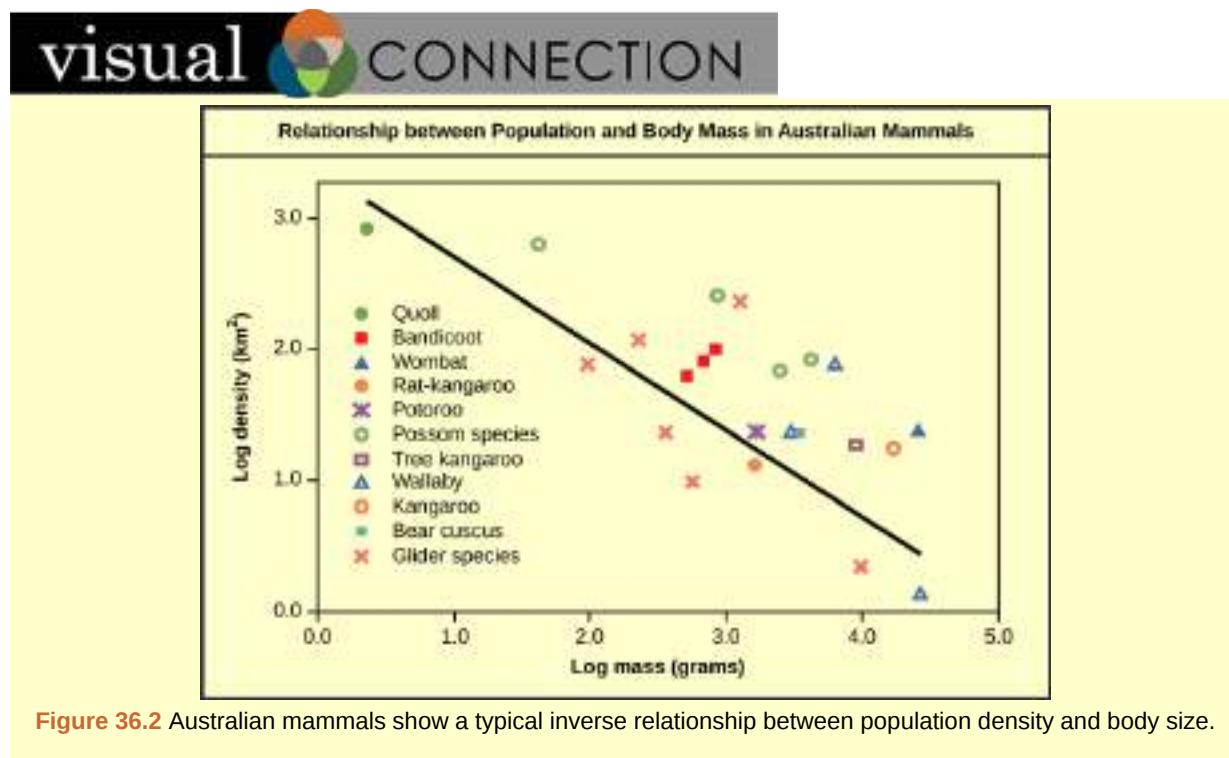

|                                   |                                                                                                                                                                                                                                       |

| <b>Big Idea 2</b>                 | Biological systems utilize free energy and molecular building blocks to grow, to reproduce, and to maintain dynamic homeostasis.                                                                                                      |
| <b>Enduring Understanding 2.D</b> | Growth and dynamic homeostasis of a biological system are influenced by changes in the system's environment.                                                                                                                          |
| <b>Essential Knowledge</b>        | <b>2.D.1</b> All biological systems from cells and organisms to populations, communities and ecosystems are affected by complex biotic and abiotic interactions involving exchange of matter and free energy.                         |
| <b>Science Practice</b>           | <b>6.4</b> The student can make claims and predictions about natural phenomena based on scientific theories and models.                                                                                                               |
| <b>Learning Objective</b>         | <b>2.3</b> The student is able to predict how changes in free energy availability affect organisms, populations, and ecosystems.                                                                                                      |
| <b>Essential Knowledge</b>        | <b>2.D.1</b> All biological systems from cells and organisms to populations, communities and ecosystems are affected by complex biotic and abiotic interactions involving exchange of matter and free energy.                         |
| <b>Science Practice</b>           | <b>1.3</b> The student can refine representations and models of natural or man-made phenomena and systems in the domain.                                                                                                              |
| <b>Science Practice</b>           | <b>3.2</b> The student can refine scientific questions.                                                                                                                                                                               |
| <b>Learning Objective</b>         | <b>2.22</b> The student is able to refine scientific models and questions about the effect of complex biotic and abiotic interactions on all biological systems, from cells and organisms to populations, communities and ecosystems. |
| <b>Essential Knowledge</b>        | <b>2.D.1</b> All biological systems from cells and organisms to populations, communities and ecosystems are affected by complex biotic and abiotic interactions involving exchange of matter and free energy.                         |

|                                   |                                                                                                                                                                                                        |
|-----------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Science Practice</b>           | 4.2 The student can design a plan for collecting data to answer a particular scientific question.                                                                                                      |
| <b>Science Practice</b>           | 7.2 The student can connect concepts in and across domain(s) to generalize or extrapolate in and/or across enduring understandings and/or big ideas.                                                   |
| <b>Learning Objective</b>         | 2.23 The student is able to design a plan for collecting data to show that all biological systems, including populations, are affected by complex biotic and abiotic interactions.                     |
| <b>Essential Knowledge</b>        | 2.D.1 All biological systems from cells and organisms to populations, communities and ecosystems are affected by complex biotic and abiotic interactions involving exchange of matter and free energy. |
| <b>Science Practice</b>           | 5.1 The student can analyze data to identify patterns or relationships.                                                                                                                                |
| <b>Learning Objective</b>         | 2.24 The student is able to analyze data to identify possible patterns and relationships between a biotic or abiotic factors and a biological system, including populations.                           |
| <b>Big Idea 4</b>                 | Biological systems interact, and these systems and their interactions possess complex properties.                                                                                                      |
| <b>Enduring Understanding 4.A</b> | Interactions within biological systems lead to complex properties.                                                                                                                                     |
| <b>Essential Knowledge</b>        | 4.A.5 Communities are composed of populations of organisms that interact in complex ways.                                                                                                              |
| <b>Science Practice</b>           | 1.4 The student can use representations and models to analyze situations or solve problems qualitatively and quantitatively.                                                                           |
| <b>Science Practice</b>           | 4.2 The student can design a plan for collecting data to answer a particular scientific question.                                                                                                      |
| <b>Learning Objective</b>         | 4.11 The student is able to justify the selection of the kind of data needed to answer scientific questions about the interaction of populations within communities.                                   |
| <b>Essential Knowledge</b>        | 4.A.5 Communities are composed of populations of organisms that interact in complex ways.                                                                                                              |
| <b>Science Practice</b>           | 2.2 The student can apply mathematical routines to quantities that describe natural phenomena.                                                                                                         |
| <b>Learning Objective</b>         | 4.12 The student is able to apply mathematical routines to quantities that describe communities composed of populations of organisms that interact in complex ways.                                    |
| <b>Essential Knowledge</b>        | 4.A.5 Communities are composed of populations of organisms that interact in complex ways.                                                                                                              |
| <b>Science Practice</b>           | 6.4 The student can make claims and predictions about natural phenomena based on scientific theories and models.                                                                                       |
| <b>Learning Objective</b>         | 4.13 The student is able to predict the effects of a change in the community's populations on the community.                                                                                           |

Populations are dynamic entities. Populations consist all of the species living within a specific area, and populations fluctuate based on a number of factors: seasonal and yearly changes in the environment, natural disasters such as forest fires and volcanic eruptions, and competition for resources between and within species. The statistical study of population dynamics, demography, uses a series of mathematical tools to investigate how populations respond to changes in their biotic and abiotic environments. Many of these tools were originally designed to study human populations. For example, **life tables**, which detail the life expectancy of individuals within a population, were initially developed by life insurance companies to set insurance rates. In fact, while the term “demographics” is commonly used when discussing humans, all living populations can be studied using this approach.

## Population Size and Density

The study of any population usually begins by determining how many individuals of a particular species exist, and how closely associated they are with each other. Within a particular habitat, a population can be characterized by its **population size ( $N$ )**, the total number of individuals, and its **population density**, the number of individuals within a specific area or volume. Population size and density are the two main characteristics used to describe and understand populations. For example, populations with more individuals may be more stable than smaller populations based on their genetic variability, and thus their potential to adapt to the environment. Alternatively, a member of a population with low population density (more spread out in the habitat), might have more difficulty finding a mate to reproduce compared to a population of higher density. As is shown in **Figure 36.2**, smaller organisms tend to be more densely distributed than larger organisms.

### Population Research Methods

The most accurate way to determine population size is to simply count all of the individuals within the habitat. However, this method is often not logically or economically feasible, especially when studying large habitats. Thus, scientists usually study populations by sampling a representative portion of each habitat and using this data to make inferences about the habitat as a whole. A variety of methods can be used to sample populations to determine their size and density. For immobile organisms such as plants, or for very small and slow-moving organisms, a **quadrat** may be used (Figure 36.3). A quadrat is a way of marking off square areas within a habitat, either by staking out an area with sticks and string, or by the use of a wood, plastic, or metal square placed on the ground. After setting the quadrats, researchers then count the number of individuals that lie within their boundaries. Multiple quadrat samples are performed throughout the habitat at several random locations. All of this data can then be used to estimate the population size and population density within the entire habitat. The number and size of quadrat samples depends on the type of organisms under study and other factors, including the density of the organism. For example, if sampling daffodils, a  $1\text{ m}^2$  quadrat might be used whereas with giant redwoods, which are larger and live much further apart from each other, a larger quadrat of  $100\text{ m}^2$  might be employed. This ensures that enough individuals of the species are counted to get an accurate sample that correlates with the habitat, including areas not sampled.

**Figure 36.3** A scientist uses a quadrat to measure population size and density. (credit: NPS Sonoran Desert Network)

For mobile organisms, such as mammals, birds, or fish, a technique called **mark and recapture** is often used. This method involves marking a sample of captured animals in some way (such as tags, bands, paint, or other body markings), and then releasing them back into the environment to allow them to mix with the rest of the population; later, a new sample is collected, including some individuals that are marked (recaptures) and some individuals that are unmarked (**Figure 36.4**).

**Figure 36.4** Mark and recapture is used to measure the population size of mobile animals such as (a) bighorn sheep, (b) the California condor, and (c) salmon. (credit a: modification of work by Neal Herbert, NPS; credit b: modification of work by Pacific Southwest Region USFWS; credit c: modification of work by Ingrid Taylor)

Using the ratio of marked and unmarked individuals, scientists determine how many individuals are in the sample. From this, calculations are used to estimate the total population size. This method assumes that the larger the population, the lower the percentage of tagged organisms that will be recaptured since they will have mixed with more untagged individuals. For example, if 80 deer are captured, tagged, and released into the forest, and later 100 deer are captured and 20 of them are already marked, we can determine the population size ( $N$ ) using the following equation:

$$\frac{(\text{number marked first catch} \times \text{total number of second catch})}{\text{number marked second catch}} = N$$

Using our example, the population size would be estimated at 400.

$$\frac{(80 \times 100)}{20} = 400$$

Therefore, there are an estimated 400 total individuals in the original population.

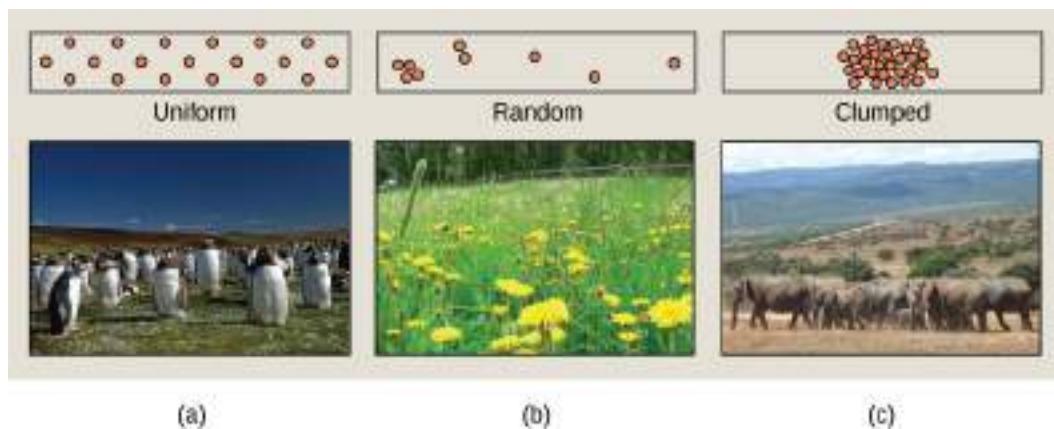

There are some limitations to the mark and recapture method. Some animals from the first catch may learn to avoid capture in the second round, thus inflating population estimates. Alternatively, animals may preferentially be retrapped (especially if a food reward is offered), resulting in an underestimate of population size. Also, some species may be harmed by the marking technique, reducing their survival. A variety of other techniques have been developed, including the electronic tracking of animals tagged with radio transmitters and the use of data from commercial fishing and trapping operations to estimate the size and health of populations and communities.

## Species Distribution

In addition to measuring simple density, further information about a population can be obtained by looking at the

distribution of the individuals. **Species dispersion patterns** (or distribution patterns) show the spatial relationship between members of a population within a habitat at a particular point in time. In other words, they show whether members of the species live close together or far apart, and what patterns are evident when they are spaced apart.

Individuals in a population can be more or less equally spaced apart, dispersed randomly with no predictable pattern, or clustered in groups. These are known as uniform, random, and clumped dispersion patterns, respectively (Figure 36.5). Uniform dispersion is observed in plants that secrete substances inhibiting the growth of nearby individuals (such as the release of toxic chemicals by the sage plant *Salvia leucophylla*, a phenomenon called allelopathy) and in animals like the penguin that maintain a defined territory. An example of random dispersion occurs with dandelion and other plants that have wind-dispersed seeds that germinate wherever they happen to fall in a favorable environment. A clumped dispersion may be seen in plants that drop their seeds straight to the ground, such as oak trees, or animals that live in groups (schools of fish or herds of elephants). Clumped dispersions may also be a function of habitat heterogeneity. Thus, the dispersion of the individuals within a population provides more information about how they interact with each other than does a simple density measurement. Just as lower density species might have more difficulty finding a mate, solitary species with a random distribution might have a similar difficulty when compared to social species clumped together in groups.

**Figure 36.5** Species may have uniform, random, or clumped distribution. Territorial birds such as penguins tend to have uniform distribution. Plants such as dandelions with wind-dispersed seeds tend to be randomly distributed. Animals such as elephants that travel in groups exhibit clumped distribution. (credit a: modification of work by Ben Tubby; credit b: modification of work by Rosendahl; credit c: modification of work by Rebecca Wood)

## Demography

While population size and density describe a population at one particular point in time, scientists must use demography to study the dynamics of a population. Demography is the statistical study of population changes over time: birth rates, death rates, and life expectancies. Each of these measures, especially birth rates, may be affected by the population characteristics described above. For example, a large population size results in a higher birth rate because more potentially reproductive individuals are present. In contrast, a large population size can also result in a higher death rate because of competition, disease, and the accumulation of waste. Similarly, a higher population density or a clumped dispersion pattern results in more potential reproductive encounters between individuals, which can increase birth rate. Lastly, a female-biased sex ratio (the ratio of males to females) or age structure (the proportion of population members at specific age ranges) composed of many individuals of reproductive age can increase birth rates.

In addition, the demographic characteristics of a population can influence how the population grows or declines over time. If birth and death rates are equal, the population remains stable. However, the population size will increase if birth rates exceed death rates; the population will decrease if birth rates are less than death rates. Life expectancy is another important factor; the length of time individuals remain in the population impacts local resources, reproduction, and the overall health of the population. These demographic characteristics are often displayed in the form of a life table.

### Life Tables

Life tables provide important information about the life history of an organism. Life tables divide the population into age groups and often sexes, and show how long a member of that group is likely to live. They are modeled after actuarial tables used by the insurance industry for estimating human life expectancy. Life tables may include the probability of individuals dying before their next birthday (i.e., their **mortality rate**), the percentage of surviving individuals dying at a particular age interval, and their life expectancy at each interval. An example of a life table is shown in **Table 36.1** from a study of Dall mountain sheep, a species native to northwestern North America. Notice that the population is divided into age intervals (column A). The mortality rate (per 1000), shown in column D, is based on the number of individuals dying during the age

interval (column B) divided by the number of individuals surviving at the beginning of the interval (Column C), multiplied by 1000.

$$\text{mortality rate} = \frac{\text{number of individuals dying}}{\text{number of individuals surviving}} \times 1000$$

For example, between ages three and four, 12 individuals die out of the 776 that were remaining from the original 1000 sheep. This number is then multiplied by 1000 to get the mortality rate per thousand.

$$\text{mortality rate} = \frac{12}{776} \times 1000 \approx 15.5$$

As can be seen from the mortality rate data (column D), a high death rate occurred when the sheep were between 6 and 12 months old, and then increased even more from 8 to 12 years old, after which there were few survivors. The data indicate that if a sheep in this population were to survive to age one, it could be expected to live another 7.7 years on average, as shown by the life expectancy numbers in column E.

**Life Table of Dall Mountain Sheep<sup>[1]</sup>**

| Age interval (years) | Number dying in age interval out of 1000 born | Number surviving at beginning of age interval out of 1000 born | Mortality rate per 1000 alive at beginning of age interval | Life expectancy or mean lifetime remaining to those attaining age interval |
|----------------------|-----------------------------------------------|----------------------------------------------------------------|------------------------------------------------------------|----------------------------------------------------------------------------|
| 0-0.5                | 54                                            | 1000                                                           | 54.0                                                       | 7.06                                                                       |

**Table 36.1** This life table of *Ovis dalli* shows the number of deaths, number of survivors, mortality rate, and life expectancy at each age interval for the Dall mountain sheep.

### Survivorship Curves

Another tool used by population ecologists is a **survivorship curve**, which is a graph of the number of individuals surviving at each age interval plotted versus time (usually with data compiled from a life table). These curves allow us to compare the life histories of different populations (Figure 36.6). Humans and most primates exhibit a Type I survivorship curve because a high percentage of offspring survive their early and middle years—death occurs predominantly in older individuals. These types of species usually have small numbers of offspring at one time, and they give a high amount of parental care to them to ensure their survival. Birds are an example of an intermediate or Type II survivorship curve because birds die more or

1. Data Adapted from Edward S. Deevey, Jr., “Life Tables for Natural Populations of Animals,” *The Quarterly Review of Biology* 22, no. 4 (December 1947): 283–314.

less equally at each age interval. These organisms also may have relatively few offspring and provide significant parental care. Trees, marine invertebrates, and most fishes exhibit a Type III survivorship curve because very few of these organisms survive their younger years; however, those that make it to an old age are more likely to survive for a relatively long period of time. Organisms in this category usually have a very large number of offspring, but once they are born, little parental care is provided. Thus these offspring are “on their own” and vulnerable to predation, but their sheer numbers assure the survival of enough individuals to perpetuate the species.

**Figure 36.6** Survivorship curves show the distribution of individuals in a population according to age. Humans and most mammals have a Type I survivorship curve because death primarily occurs in the older years. Birds have a Type II survivorship curve, as death at any age is equally probable. Trees have a Type III survivorship curve because very few survive the younger years, but after a certain age, individuals are much more likely to survive.

### Activity

Design an investigation that a researcher might use to determine the size of a penguin population in the Antarctic using the mark and release method. What biotic or abiotic factors might influence the size of the penguin population in a given area?

## Section Summary

Populations are individuals of a species that live in a particular habitat. Ecologists measure characteristics of populations: size, density, dispersion pattern, age structure, and sex ratio. Life tables are useful to calculate life expectancies of individual population members. Survivorship curves show the number of individuals surviving at each age interval plotted versus time.

## 36.2 | Life Histories and Natural Selection

In this section, you will explore the following questions:

- How are life history patterns influenced by natural selection?
- What are different life history patterns, and how do different reproductive strategies affect species survival?

## Connection for AP® Courses

All living systems, including populations, require free energy to maintain order, to grow and to reproduce. As we learned in

earlier chapters, changes in free energy availability can cause fluctuations in population. All species have an **energy budget** and must balance energy intake with their use of energy for metabolism, parental care, and energy storage.

It's amazing how much free energy is required for reproduction and the subsequent care of offspring. Fecundity describes how many offspring could be produced if an individual has as many offspring as possible. In animals, fecundity is inversely proportional to the amount of care given to an individual offspring.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 1 and Big Idea 2 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Learning Objective</b>         | <b>2.1</b> The student is able to explain how biological systems use free energy based on empirical data that all organisms require constant energy input to maintain organization, to grow and to reproduce. |

A species' **life history** describes the series of events over its lifetime, such as how resources are allocated for growth, maintenance, and reproduction. Life history traits affect the life table of an organism. A species' life history is genetically determined and shaped by the environment and natural selection.

## Life History Patterns and Energy Budgets

Energy is required by all living organisms for their growth, maintenance, and reproduction; at the same time, energy is often a major limiting factor in determining an organism's survival. Plants, for example, acquire energy from the sun via photosynthesis, but must expend this energy to grow, maintain health, and produce energy-rich seeds to produce the next generation. Animals have the additional burden of using some of their energy reserves to acquire food. Furthermore, some animals must expend energy caring for their offspring. Thus, all species have an energy budget: they must balance energy intake with their use of energy for metabolism, reproduction, parental care, and energy storage (such as bears building up body fat for winter hibernation).

### Parental Care and Fecundity

**Fecundity** is the potential reproductive capacity of an individual within a population. In other words, fecundity describes how many offspring could ideally be produced if an individual has as many offspring as possible, repeating the reproductive

cycle as soon as possible after the birth of the offspring. In animals, fecundity is inversely related to the amount of parental care given to an individual offspring. Species, such as many marine invertebrates, that produce many offspring usually provide little if any care for the offspring (they would not have the energy or the ability to do so anyway). Most of their energy budget is used to produce many tiny offspring. Animals with this strategy are often self-sufficient at a very early age. This is because of the energy tradeoff these organisms have made to maximize their evolutionary fitness. Because their energy is used for producing offspring instead of parental care, it makes sense that these offspring have some ability to be able to move within their environment and find food and perhaps shelter. Even with these abilities, their small size makes them extremely vulnerable to predation, so the production of many offspring allows enough of them to survive to maintain the species.

Animal species that have few offspring during a reproductive event usually give extensive parental care, devoting much of their energy budget to these activities, sometimes at the expense of their own health. This is the case with many mammals, such as humans, kangaroos, and pandas. The offspring of these species are relatively helpless at birth and need to develop before they achieve self-sufficiency.

Plants with low fecundity produce few energy-rich seeds (such as coconuts and chestnuts) with each having a good chance to germinate into a new organism; plants with high fecundity usually have many small, energy-poor seeds (like orchids) that have a relatively poor chance of surviving. Although it may seem that coconuts and chestnuts have a better chance of surviving, the energy tradeoff of the orchid is also very effective. It is a matter of where the energy is used, for large numbers of seeds or for fewer seeds with more energy.

### ***Early versus Late Reproduction***

The timing of reproduction in a life history also affects species survival. Organisms that reproduce at an early age have a greater chance of producing offspring, but this is usually at the expense of their growth and the maintenance of their health. Conversely, organisms that start reproducing later in life often have greater fecundity or are better able to provide parental care, but they risk that they will not survive to reproductive age. Examples of this can be seen in fishes. Small fish like guppies use their energy to reproduce rapidly, but never attain the size that would give them defense against some predators. Larger fish, like the bluegill or shark, use their energy to attain a large size, but do so with the risk that they will die before they can reproduce or at least reproduce to their maximum. These different energy strategies and tradeoffs are key to understanding the evolution of each species as it maximizes its fitness and fills its niche. In terms of energy budgeting, some species “blow it all” and use up most of their energy reserves to reproduce early before they die. Other species delay having reproduction to become stronger, more experienced individuals and to make sure that they are strong enough to provide parental care if necessary.

### ***Single versus Multiple Reproductive Events***

Some life history traits, such as fecundity, timing of reproduction, and parental care, can be grouped together into general strategies that are used by multiple species. **Semelparity** occurs when a species reproduces only once during its lifetime and then dies. Such species use most of their resource budget during a single reproductive event, sacrificing their health to the point that they do not survive. Examples of semelparity are bamboo, which flowers once and then dies, and the Chinook salmon ([Figure 36.7a](#)), which uses most of its energy reserves to migrate from the ocean to its freshwater nesting area, where it reproduces and then dies. Scientists have posited alternate explanations for the evolutionary advantage of the Chinook’s post-reproduction death: a programmed suicide caused by a massive release of corticosteroid hormones, presumably so the parents can become food for the offspring, or simple exhaustion caused by the energy demands of reproduction; these are still being debated.

**Iteroparity** describes species that reproduce repeatedly during their lives. Some animals are able to mate only once per year, but survive multiple mating seasons. The pronghorn antelope is an example of an animal that goes into a seasonal estrus cycle (“heat”): a hormonally induced physiological condition preparing the body for successful mating ([Figure 36.7b](#)). Females of these species mate only during the estrus phase of the cycle. A different pattern is observed in primates, including humans and chimpanzees, which may attempt reproduction at any time during their reproductive years, even though their menstrual cycles make pregnancy likely only a few days per month during ovulation ([Figure 36.7c](#)).

## Energy Budgets, Reproductive Costs, and Sexual Selection in *Drosophila*

Research into how animals allocate their energy resources for growth, maintenance, and reproduction has used a variety of experimental animal models. Some of this work has been done using the common fruit fly, *Drosophila melanogaster*. Studies have shown that not only does reproduction have a cost as far as how long male fruit flies live, but also fruit flies that have already mated several times have limited sperm remaining for reproduction. Fruit flies maximize their last chances at reproduction by selecting optimal mates.

In a 1981 study, male fruit flies were placed in enclosures with either virgin or inseminated females. The males that mated with virgin females had shorter life spans than those in contact with the same number of inseminated females with which they were unable to mate. This effect occurred regardless of how large (indicative of their age) the males were. Thus, males that did not mate lived longer, allowing them more opportunities to find mates in the future.

More recent studies, performed in 2006, show how males select the female with which they will mate and how this is affected by previous matings (Figure 36.8).<sup>[2]</sup> Males were allowed to select between smaller and larger females. Findings showed that larger females had greater fecundity, producing twice as many offspring per mating as the smaller females did. Males that had previously mated, and thus had lower supplies of sperm, were termed “resource-depleted,” while males that had not mated were termed “non-resource-depleted.” The study showed that although non-resource-depleted males preferentially mated with larger females, this selection of partners was more pronounced in the resource-depleted males. Thus, males with depleted sperm supplies, which were limited in the number of times that they could mate before they replenished their sperm supply, selected larger, more fecund females, thus maximizing their chances for offspring. This study was one of the first to show that the physiological state of the male affected its mating behavior in a way that clearly maximizes its use of limited reproductive resources.

|                    | Ratio large/small females mated |
|--------------------|---------------------------------|
| Non sperm-depleted | 8 ± 5                           |
| Sperm-depleted     | 15 ± 5                          |

**Figure 36.8** Male fruit flies that had previously mated (sperm-depleted) picked larger, more fecund females more often than those that had not mated (non-sperm-depleted). This change in behavior causes an increase in the efficiency of a limited reproductive resource: sperm.

These studies demonstrate two ways in which the energy budget is a factor in reproduction. First, energy expended on mating may reduce an animal's lifespan, but by this time they have already reproduced, so in the context of natural selection this early death is not of much evolutionary importance. Second, when resources such as sperm (and the energy needed to replenish it) are low, an organism's behavior can change to give them the best chance of passing their genes on to the next generation. These changes in behavior, so important to evolution, are studied in a discipline known as behavioral biology, or ethology, at the interface between population biology and psychology.

Discuss how natural selection might influence the phenomenon revealed by this study.

- Sperm-depleted males were successful in producing offspring when mated with small females. So, the genes that influenced the behavior of sperm-depleted males to choose larger, more fecund females were selected.
- Sperm-depleted males were successful in producing offspring when mated with large females. So, the genes that influenced the behavior of sperm-depleted males to choose smaller, more fecund females were selected.
- Sperm-depleted males were successful in producing offspring when mated with large females. So, the genes that influenced the behavior of sperm-depleted males to choose larger, more fecund females were selected.
- Sperm-depleted males were successful in producing offspring when mated with smaller females. So, the genes that influenced the behavior of sperm-depleted males to choose smaller, less fecund females were selected.

selected.

### Think About It

Why is long-term parental care not associated with having many offspring during a reproductive episode?

### Section Summary

All species have evolved a pattern of living, called a life history strategy, in which they partition energy for growth, maintenance, and reproduction. These patterns evolve through natural selection; they allow species to adapt to their environment to obtain the resources they need to successfully reproduce. There is an inverse relationship between fecundity and parental care. A species may reproduce early in life to ensure surviving to a reproductive age or reproduce later in life to become larger and healthier and better able to give parental care. A species may reproduce once (semelparity) or many times (iteroparity) in its life.

## 36.3 | Environmental Limits to Population Growth

In this section, you will explore the following questions:

- What are the characteristics of and differences between exponential and logistic growth patterns?
- What are examples of exponential and logistic growth in natural populations?

### Connection for AP<sup>®</sup> Courses

Population ecologists use mathematical methods to model population dynamics. These models can be used to describe changes occurring in a population and to better predict future changes. Applying mathematics to these models (and being able to manipulate the equations) is in scope for AP<sup>®</sup>. (Remember that for the AP<sup>®</sup> Exam you will have access to a formula sheet with these equations.)

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 4 of the AP<sup>®</sup> Biology Curriculum Framework. The AP<sup>®</sup> Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

Although life histories describe the way many characteristics of a population (such as their age structure) change over time in a general way, population ecologists make use of a variety of methods to model population dynamics mathematically. These more precise models can then be used to accurately describe changes occurring in a population and better predict future changes. Certain models that have been accepted for decades are now being modified or even abandoned due to their lack of predictive ability, and scholars strive to create effective new models.

## Exponential Growth

Charles Darwin, in his theory of natural selection, was greatly influenced by the English clergyman Thomas Malthus. Malthus published a book in 1798 stating that populations with unlimited natural resources grow very rapidly, and then population growth decreases as resources become depleted. This accelerating pattern of increasing population size is called **exponential growth**.

The best example of exponential growth is seen in bacteria. Bacteria are prokaryotes that reproduce by prokaryotic fission. This division takes about an hour for many bacterial species. If 1000 bacteria are placed in a large flask with an unlimited supply of nutrients (so the nutrients will not become depleted), after an hour, there is one round of division and each organism divides, resulting in 2000 organisms—an increase of 1000. In another hour, each of the 2000 organisms will double, producing 4000, an increase of 2000 organisms. After the third hour, there should be 8000 bacteria in the flask, an increase of 4000 organisms. The important concept of exponential growth is that the **population growth rate**—the number of organisms added in each reproductive generation—is accelerating; that is, it is increasing at a greater and greater rate. After 1 day and 24 of these cycles, the population would have increased from 1000 to more than 16 billion. When the population size,  $N$ , is plotted over time, a **J-shaped growth curve** is produced ([Figure 36.9](#)).

The bacteria example is not representative of the real world where resources are limited. Furthermore, some bacteria will die during the experiment and thus not reproduce, lowering the growth rate. Therefore, when calculating the growth rate of a population, the **death rate (D)** (number organisms that die during a particular time interval) is subtracted from the **birth rate (B)** (number organisms that are born during that interval). This is shown in the following formula:

$$\frac{\Delta N \text{ (change in number)}}{\Delta T \text{ (change in time)}} = B \text{ (birth rate)} - D \text{ (death rate)}$$

The birth rate is usually expressed on a per capita (for each individual) basis. Thus,  $B$  (birth rate) =  $bN$  (the per capita birth rate “ $b$ ” multiplied by the number of individuals “ $N$ ”) and  $D$  (death rate) =  $dN$  (the per capita death rate “ $d$ ” multiplied by the number of individuals “ $N$ ”). Additionally, ecologists are interested in the population at a particular point in time, an infinitely small time interval. For this reason, the terminology of differential calculus is used to obtain the “instantaneous” growth rate, replacing the *change* in number and time with an instant-specific measurement of number and time.

$$\frac{dN}{dT} = bN - dN = (b - d)N$$

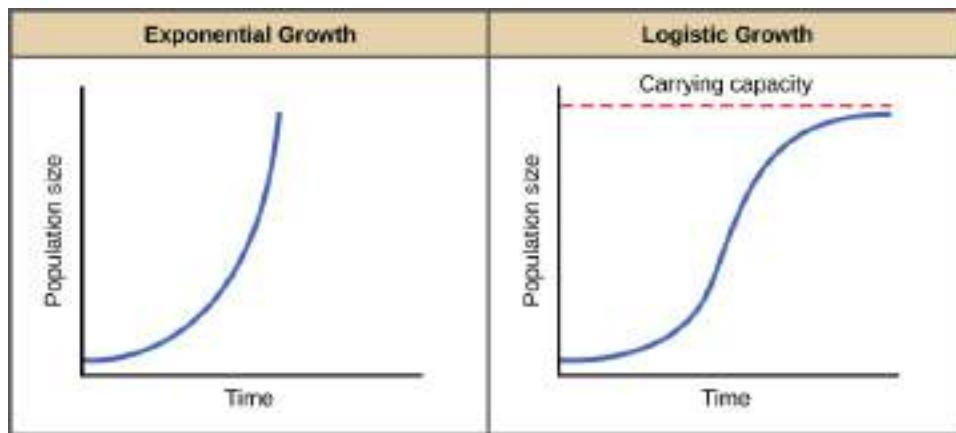

Notice that the “ $d$ ” associated with the first term refers to the derivative (as the term is used in calculus) and is different from the death rate, also called “ $d$ .” The difference between birth and death rates is further simplified by substituting the term “ $r$ ” (intrinsic rate of increase) for the relationship between birth and death rates:

$$\frac{dN}{dT} = rN$$

The value “ $r$ ” can be positive, meaning the population is increasing in size; or negative, meaning the population is decreasing in size; or zero, where the population’s size is unchanging, a condition known as **zero population growth**. A further refinement of the formula recognizes that different species have inherent differences in their intrinsic rate of increase (often thought of as the potential for reproduction), even under ideal conditions. Obviously, a bacterium can reproduce

more rapidly and have a higher intrinsic rate of growth than a human. The maximal growth rate for a species is its **biotic potential, or  $r_{max}$** , thus changing the equation to:

$$\frac{dN}{dT} = r_{max} N$$

**Figure 36.9** When resources are unlimited, populations exhibit exponential growth, resulting in a J-shaped curve. When resources are limited, populations exhibit logistic growth. In logistic growth, population expansion decreases as resources become scarce, and it levels off when the carrying capacity of the environment is reached, resulting in an S-shaped curve.

## Logistic Growth

Exponential growth is possible only when infinite natural resources are available; this is not the case in the real world. Charles Darwin recognized this fact in his description of the “struggle for existence,” which states that individuals will compete (with members of their own or other species) for limited resources. The successful ones will survive to pass on their own characteristics and traits (which we know now are transferred by genes) to the next generation at a greater rate (natural selection). To model the reality of limited resources, population ecologists developed the **logistic growth** model.

### Carrying Capacity and the Logistic Model

In the real world, with its limited resources, exponential growth cannot continue indefinitely. Exponential growth may occur in environments where there are few individuals and plentiful resources, but when the number of individuals gets large enough, resources will be depleted, slowing the growth rate. Eventually, the growth rate will plateau or level off (**Figure 36.9**). This population size, which represents the maximum population size that a particular environment can support, is called the **carrying capacity, or  $K$** .

The formula we use to calculate logistic growth adds the carrying capacity as a moderating force in the growth rate. The expression “ $K - N$ ” is indicative of how many individuals may be added to a population at a given stage, and “ $K - N$ ” divided by “ $K$ ” is the fraction of the carrying capacity available for further growth. Thus, the exponential growth model is restricted by this factor to generate the logistic growth equation:

$$\frac{dN}{dT} = r_{max} \frac{dN}{dT} = r_{max} N \frac{(K - N)}{K}$$

Notice that when  $N$  is very small,  $(K-N)/K$  becomes close to  $K/K$  or 1, and the right side of the equation reduces to  $r_{max}N$ , which means the population is growing exponentially and is not influenced by carrying capacity. On the other hand, when  $N$  is large,  $(K-N)/K$  come close to zero, which means that population growth will be slowed greatly or even stopped. Thus, population growth is greatly slowed in large populations by the carrying capacity  $K$ . This model also allows for the population of a negative population growth, or a population decline. This occurs when the number of individuals in the population exceeds the carrying capacity (because the value of  $(K-N)/K$  is negative).

A graph of this equation yields an **S-shaped curve** (**Figure 36.9**), and it is a more realistic model of population growth than exponential growth. There are three different sections to an S-shaped curve. Initially, growth is exponential because there are few individuals and ample resources available. Then, as resources begin to become limited, the growth rate decreases. Finally, growth levels off at the carrying capacity of the environment, with little change in population size over time.

### Role of Intraspecific Competition

The logistic model assumes that every individual within a population will have equal access to resources and, thus, an equal chance for survival. For plants, the amount of water, sunlight, nutrients, and the space to grow are the important resources,

whereas in animals, important resources include food, water, shelter, nesting space, and mates.

In the real world, phenotypic variation among individuals within a population means that some individuals will be better adapted to their environment than others. The resulting competition between population members of the same species for resources is termed **intraspecific competition** (intra- = “within”; -specific = “species”). Intraspecific competition for resources may not affect populations that are well below their carrying capacity—resources are plentiful and all individuals can obtain what they need. However, as population size increases, this competition intensifies. In addition, the accumulation of waste products can reduce an environment’s carrying capacity.

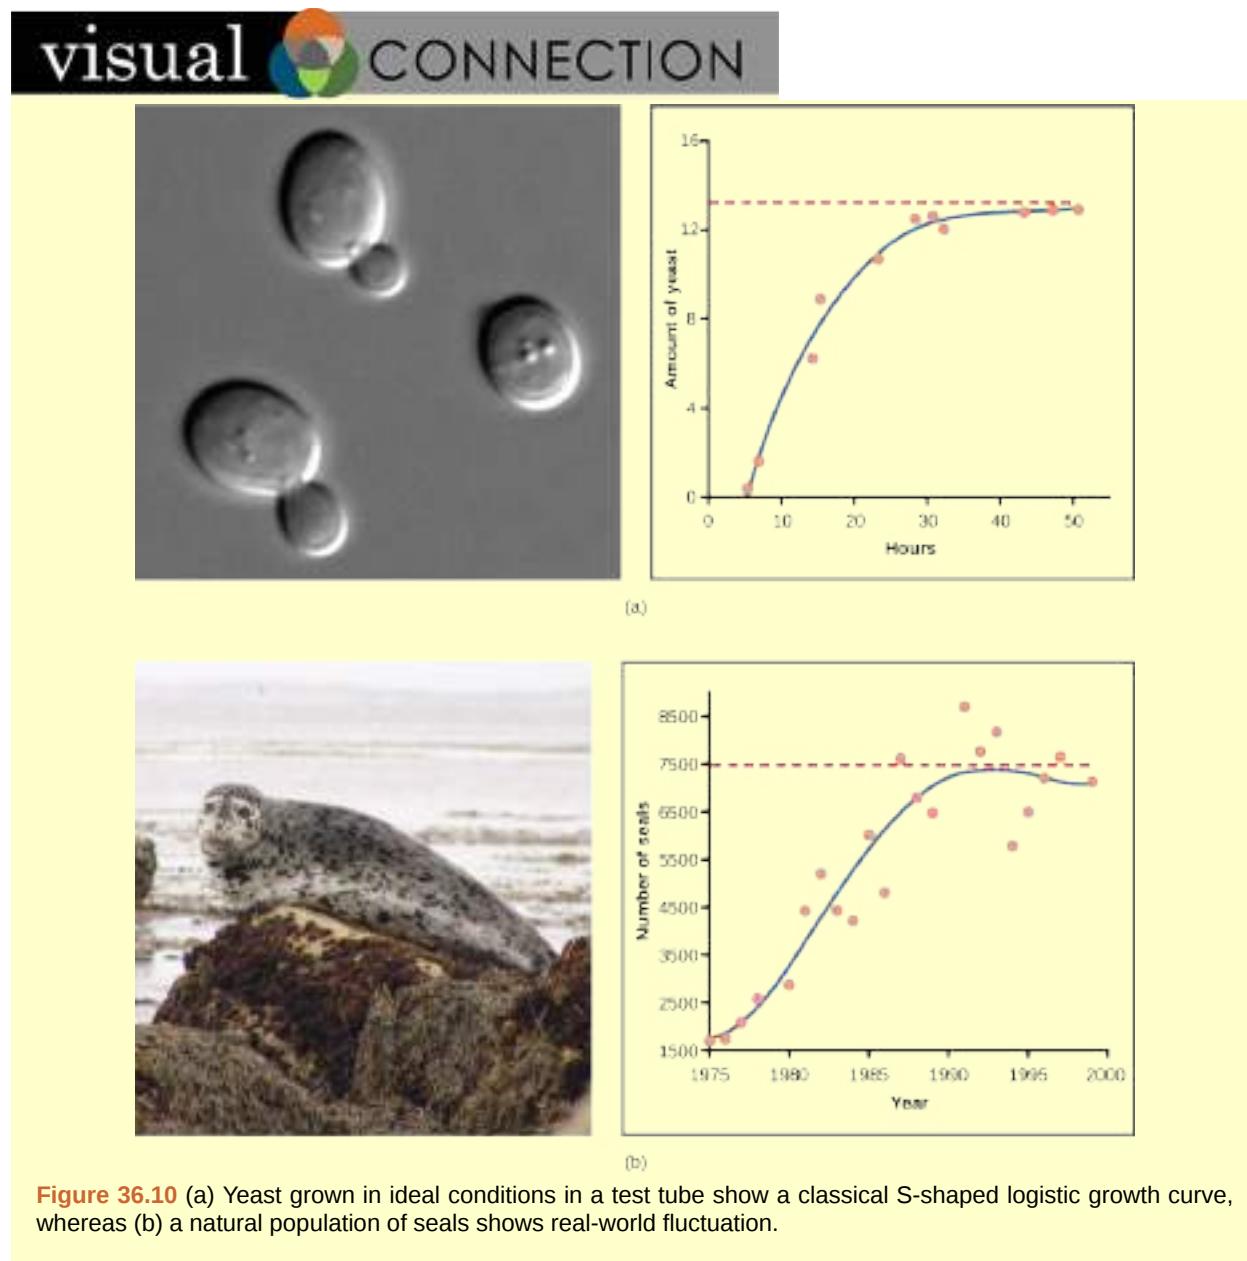

#### **Examples of Logistic Growth**

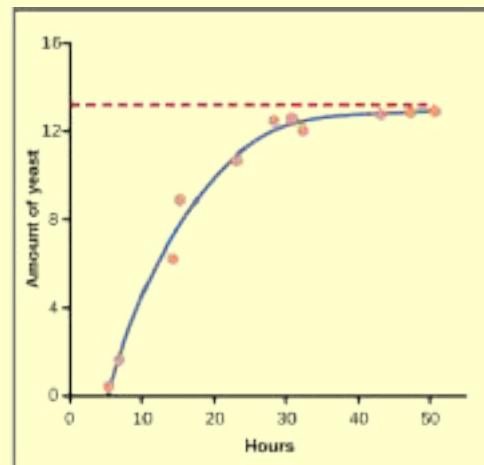

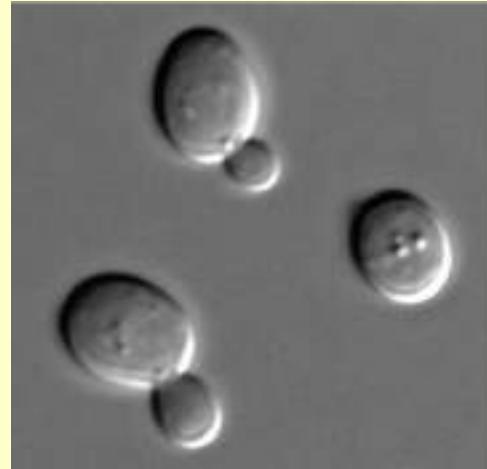

Yeast, a microscopic fungus used to make bread, exhibits the classical S-shaped curve when grown in a test tube (**Figure 36.10a**). Its growth levels off as the population depletes the nutrients that are necessary for its growth. In the real world, however, there are variations to this idealized curve. Examples in wild populations include sheep and harbor seals (**Figure 36.10b**). In both examples, the population size exceeds the carrying capacity for short periods of time and then falls below the carrying capacity afterwards. This fluctuation in population size continues to occur as the population oscillates around its carrying capacity. Still, even with this oscillation, the logistic model is confirmed.

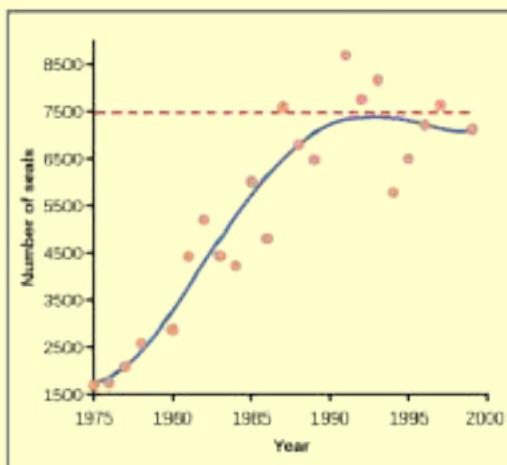

#### **Think About It**

Describe the rate of population growth that would be expected at various parts of the S-shaped curve of logistic growth.

(a)

(b)

Explain the underlying reasons for the differences in the two curves shown in these examples.

- Yeast is grown under ideal conditions, so the curve reflects limitations of resources in the controlled environment. Seals live in a natural habitat where the same types of resources are limited; but, they face other pressures like migration and changing weather.
- Yeast is grown under natural conditions, so the curve reflects limitations of resources due to the environment. Seals were also observed in natural conditions; but, there were more pressures in addition to the limitation of resources like migration and changing weather.
- Yeast is grown under ideal conditions, so the curve reflects limitations of resources in the uncontrolled environment. Seals live in a natural environment where same types of resources are limited; but they face other pressures like migration and changing weather.
- Yeast is grown under ideal conditions, so the curve reflects limitations of resources in the controlled environment. Seals live in a natural environment where the same types of resources are limited; but, they face another pressure of migration of seals out of the population.

## Section Summary

Populations with unlimited resources grow exponentially, with an accelerating growth rate. When resources become limiting, populations follow a logistic growth curve. The population of a species will level off at the carrying capacity of its environment.

## 36.4 | Population Dynamics and Regulation

In this section, you will investigate the following questions:

- How can the carrying capacity of a habitat change?
- What are the similarities and differences between density-dependent growth regulation and density-independent growth regulation, and what are some examples of both?
- How do natural selection and environmental adaptation lead to the evolution of particular life-history patterns?

### Connection for AP® Courses

While looking at the logistic model is very useful when studying population dynamics, additional methods are used when considering more complex situations, such as changes in the carrying capacity of the environment. Abiotic and biotic factors can affect the growth and death rates of a population, so these fluctuations also require consideration when modeling a population's change over time. Sometimes, scientists need to consider how reproductive strategies play a part into the dynamics of a population over time. To consider how these different factors interact, populations are looked at from a variety of perspectives.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Learning Objective</b>         | <b>4.11</b> The student is able to justify the selection of the kind of data needed to answer scientific questions about the interactions of populations within communities. |

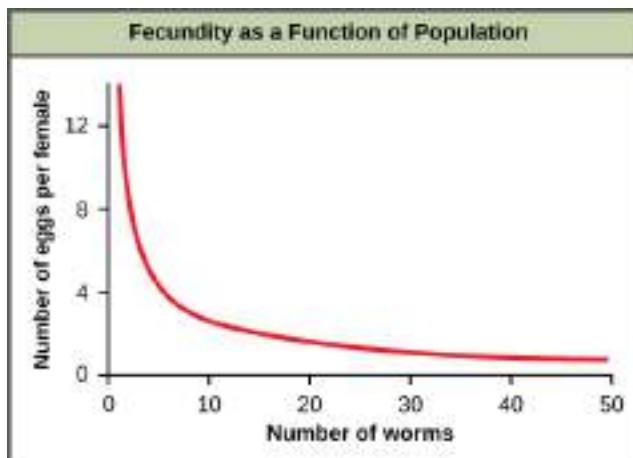

The logistic model of population growth, while valid in many natural populations and a useful model, is a simplification of real-world population dynamics. Implicit in the model is that the carrying capacity of the environment does not change, which is not the case. The carrying capacity varies annually: for example, some summers are hot and dry whereas others are cold and wet. In many areas, the carrying capacity during the winter is much lower than it is during the summer. Also, natural events such as earthquakes, volcanoes, and fires can alter an environment and hence its carrying capacity. Additionally, populations do not usually exist in isolation. They engage in **interspecific competition**: that is, they share the environment with other species, competing with them for the same resources. These factors are also important to understanding how a specific population will grow.

Nature regulates population growth in a variety of ways. These are grouped into **density-dependent** factors, in which the density of the population at a given time affects growth rate and mortality, and **density-independent** factors, which influence mortality in a population regardless of population density. Note that in the former, the effect of the factor on the population depends on the density of the population at onset. Conservation biologists want to understand both types because this helps them manage populations and prevent extinction or overpopulation.

## Density-dependent Regulation

Most density-dependent factors are biological in nature (biotic), and include predation, inter- and intraspecific competition, accumulation of waste, and diseases such as those caused by parasites. Usually, the denser a population is, the greater its mortality rate. For example, during intra- and interspecific competition, the reproductive rates of the individuals will usually be lower, reducing their population's rate of growth. In addition, low prey density increases the mortality of its predator because it has more difficulty locating its food source.

An example of density-dependent regulation is shown in **Figure 36.11** with results from a study focusing on the giant intestinal roundworm (*Ascaris lumbricoides*), a parasite of humans and other mammals.<sup>[3]</sup> Denser populations of the parasite exhibited lower fecundity: they contained fewer eggs. One possible explanation for this is that females would be smaller in more dense populations (due to limited resources) and that smaller females would have fewer eggs. This hypothesis was tested and disproved in a 2009 study which showed that female weight had no influence.<sup>[4]</sup> The actual cause of the density-dependence of fecundity in this organism is still unclear and awaiting further investigation.

**Figure 36.11** In this population of roundworms, fecundity (number of eggs) decreases with population density.<sup>[5]</sup>

## everyday CONNECTION for AP<sup>®</sup> Courses

One of the consequences of an overly dense population is the spread of disease. The brown bat pictured below has a contagious fungal infection called white nose syndrome.

**Figure 36.12** (credit: U.S. Fish and Wildlife Service Headquarters)

How would infection of zebras by *Bacillus anthracis* be described—as a density-dependent or density-independent factor that regulates population growth?

- a. This is an example of a density-independent factor because it becomes worse as the population density increases.
- b. This is an example of a density-dependent factor because it becomes better as the population density increases.
- c. This is an example of a density-dependent factor because it becomes worse as the population density increases.
- d. This is an example of a density-independent factor since it becomes better as the population density increases.

## Density-independent Regulation and Interaction with Density-dependent Factors

Many factors, typically physical or chemical in nature (abiotic), influence the mortality of a population regardless of its density, including weather, natural disasters, and pollution. An individual deer may be killed in a forest fire regardless of how many deer happen to be in that area. Its chances of survival are the same whether the population density is high or low. The same holds true for cold winter weather.

In real-life situations, population regulation is very complicated and density-dependent and independent factors can interact. A dense population that is reduced in a density-independent manner by some environmental factor(s) will be able to recover differently than a sparse population. For example, a population of deer affected by a harsh winter will recover faster if there are more deer remaining to reproduce.

## Why Did the Woolly Mammoth Go Extinct?

**Figure 36.13** The three photos include: (a) 1916 mural of a mammoth herd from the American Museum of Natural History, (b) the only stuffed mammoth in the world, from the Museum of Zoology located in St. Petersburg, Russia, and (c) a one-month-old baby mammoth, named Lyuba, discovered in Siberia in 2007. (credit a: modification of work by Charles R. Knight; credit b: modification of work by "Tanapon"/Flickr; credit c: modification of work by Matt Howry)

It's easy to get lost in the discussion of dinosaurs and theories about why they went extinct 65 million years ago. Was it due to a meteor slamming into Earth near the coast of modern-day Mexico, or was it from some long-term weather cycle that is not yet understood? One hypothesis that will never be proposed is that humans had something to do with it. Mammals were small, insignificant creatures of the forest 65 million years ago, and no humans existed.

Woolly mammoths, however, began to go extinct about 10,000 years ago, when they shared the Earth with humans who were no different anatomically than humans today (**Figure 36.13**). Mammoths survived in isolated island populations as recently as 1700 BC. We know a lot about these animals from carcasses found frozen in the ice of Siberia and other regions of the north. Scientists have sequenced at least 50 percent of its genome and believe mammoths are between 98 and 99 percent identical to modern elephants.

It is commonly thought that climate change and human hunting led to their extinction. A 2008 study estimated that climate change reduced the mammoth's range from 3,000,000 square miles 42,000 years ago to 310,000 square miles 6,000 years ago.<sup>[6]</sup> It is also well documented that humans hunted these animals. A 2012 study showed that no single factor was exclusively responsible for the extinction of these magnificent creatures.<sup>[7]</sup> In addition to human hunting, climate change, and reduction of habitat, these scientists demonstrated another important factor in the mammoth's extinction was the migration of humans across the Bering Strait to North America during the last ice age 20,000 years ago.

The maintenance of stable populations was and is very complex, with many interacting factors determining the outcome. It is important to remember that humans are also part of nature. Once we contributed to a species' decline using primitive hunting technology only.

Explain the factors that may have contributed to the extinction of the woolly mammoth, and caused it to occur over a long period of time.

- Deforestation affected the ability of the woolly mammoth to find adequate habitat and food, and humans contributed to declines in their population by hunting them.
- Climate change affected the ability of the woolly mammoth to find adequate habitat and food, and humans contributed to the decline in their population by hunting them.
- Climate change affected the ability of the woolly mammoth to find adequate food even though they had plenty of habitat, and humans contributed to declines in their population by hunting them.
- Climate change affected the ability of the woolly mammoth to find adequate habitat and food, and a plague affected Earth during that time causing their extinction.

## Life Histories of *K*-selected and *r*-selected Species

While reproductive strategies play a key role in life histories, they do not account for important factors like limited resources and competition. The regulation of population growth by these factors can be used to introduce a classical concept in population biology, that of *K*-selected versus *r*-selected species.

### **Early Theories about Life History: *K*-selected and *r*-selected Species**

By the second half of the twentieth century, the concept of *K*- and *r*-selected species was used extensively and successfully to study populations. The concept relates not only reproductive strategies, but also to a species' habitat and behavior, especially in the way that they obtain resources and care for their young. It includes length of life and survivorship factors as well. For this analysis, population biologists have grouped species into the two large categories—*K*-selected and *r*-selected—although they are really two ends of a continuum.

***K*-selected species** are species selected by stable, predictable environments. Populations of *K*-selected species tend to exist close to their carrying capacity (hence the term *K*-selected) where intraspecific competition is high. These species have few, large offspring, a long gestation period, and often give long-term care to their offspring (Table B45\_04\_01). While larger in size when born, the offspring are relatively helpless and immature at birth. By the time they reach adulthood, they must develop skills to compete for natural resources. In plants, scientists think of parental care more broadly: how long fruit takes to develop or how long it remains on the plant are determining factors in the time to the next reproductive event. Examples of *K*-selected species are primates (including humans), elephants, and plants such as oak trees (Figure 36.14a).

Oak trees grow very slowly and take, on average, 20 years to produce their first seeds, known as acorns. As many as 50,000 acorns can be produced by an individual tree, but the germination rate is low as many of these rot or are eaten by animals such as squirrels. In some years, oaks may produce an exceptionally large number of acorns, and these years may be on a two- or three-year cycle depending on the species of oak (*r*-selection).

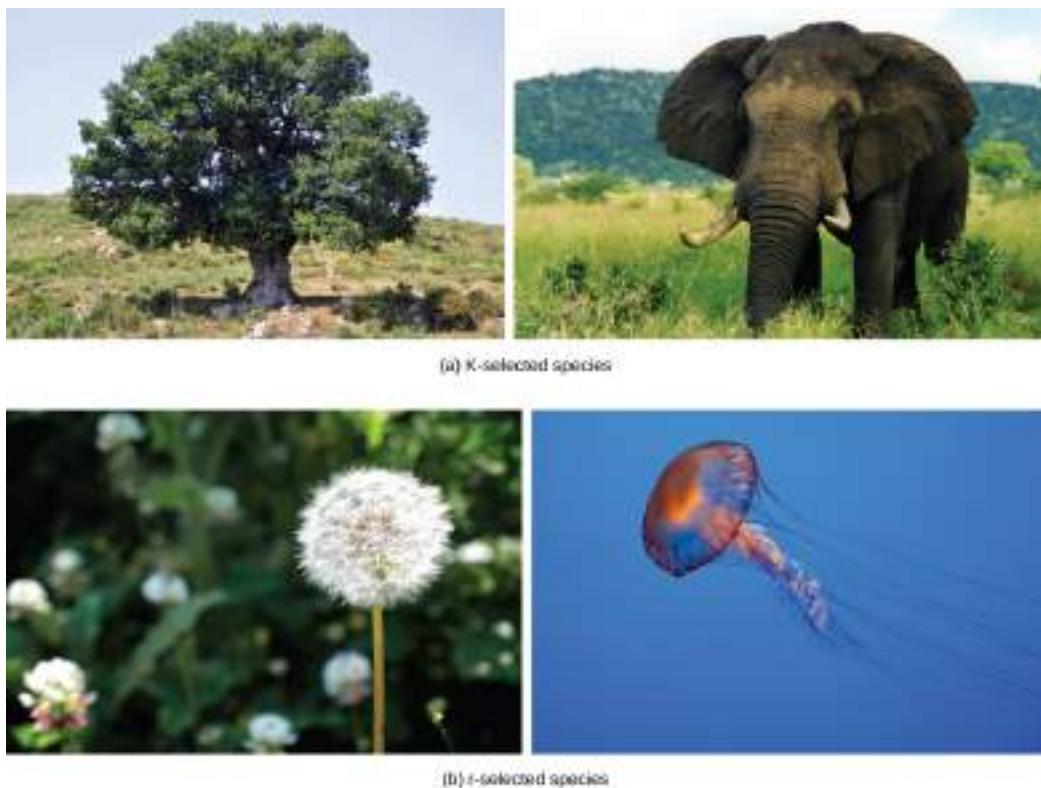

As oak trees grow to a large size and for many years before they begin to produce acorns, they devote a large percentage of their energy budget to growth and maintenance. The tree's height and size allow it to dominate other plants in the competition for sunlight, the oak's primary energy resource. Furthermore, when it does reproduce, the oak produces large, energy-rich seeds that use their energy reserve to become quickly established (*K*-selection).

In contrast, ***r*-selected species** have a large number of small offspring (hence their *r* designation (Table 36.2)). This strategy is often employed in unpredictable or changing environments. Animals that are *r*-selected do not give long-term parental care and the offspring are relatively mature and self-sufficient at birth. Examples of *r*-selected species are marine invertebrates, such as jellyfish, and plants, such as the dandelion (Figure 36.14b). Dandelions have small seeds that are wind dispersed long distances. Many seeds are produced simultaneously to ensure that at least some of them reach a hospitable environment. Seeds that land in inhospitable environments have little chance for survival since their seeds are low in energy content. Note that survival is not necessarily a function of energy stored in the seed itself.

### Characteristics of *K*-selected and *r*-selected species

| Characteristics of <i>K</i> -selected species | Characteristics of <i>r</i> -selected species |
|-----------------------------------------------|-----------------------------------------------|
| Mature late                                   | Mature early                                  |
| Greater longevity                             | Lower longevity                               |
| Increased parental care                       | Decreased parental care                       |
| Increased competition                         | Decreased competition                         |
| Fewer offspring                               | More offspring                                |
| Larger offspring                              | Smaller offspring                             |

**Table 36.2**

**Figure 36.14** (a) Elephants are considered K-selected species as they live long, mature late, and provide long-term parental care to few offspring. Oak trees produce many offspring that do not receive parental care, but are considered K-selected species based on longevity and late maturation. (b) Dandelions and jellyfish are both considered r-selected species as they mature early, have short lifespans, and produce many offspring that receive no parental care.

## Modern Theories of Life History

The *r*- and *K*-selection theory, although accepted for decades and used for much groundbreaking research, has now been reconsidered, and many population biologists have abandoned or modified it. Over the years, several studies attempted to confirm the theory, but these attempts have largely failed. Many species were identified that did not follow the theory's predictions. Furthermore, the theory ignored the age-specific mortality of the populations which scientists now know is very important. New **demographic-based models** of life history evolution have been developed which incorporate many ecological concepts included in *r*- and *K*-selection theory as well as population age structure and mortality factors.

### Section Summary

Populations are regulated by a variety of density-dependent and density-independent factors. Species are divided into two categories based on a variety of features of their life history patterns: *r*-selected species, which have large numbers of offspring, and *K*-selected species, which have few offspring. The *r*- and *K*-selection theory has fallen out of use; however, many of its key features are still used in newer, demographically-based models of population dynamics.

## 36.5 | Human Population Growth

In this section, you will investigate the following questions:

- How can human population growth be exponential?
- How have humans expanded the carrying capacity of their habitat?
- How do population growth and age structure relate to the level of economic development in different countries?
- What are the long-term implications of unchecked human population growth?

## Connection for AP® Courses

The methods used to look at animal population dynamics can also be used to look at the human populations. Like animals, humans are affected by abiotic and biotic factors. Unlike animals, humans have the ability to manipulate the factors affecting the growth of their population. As a result, additional factors come into play when studying human population dynamics. When studying projections of human population growth, ethical questions can also come to light.

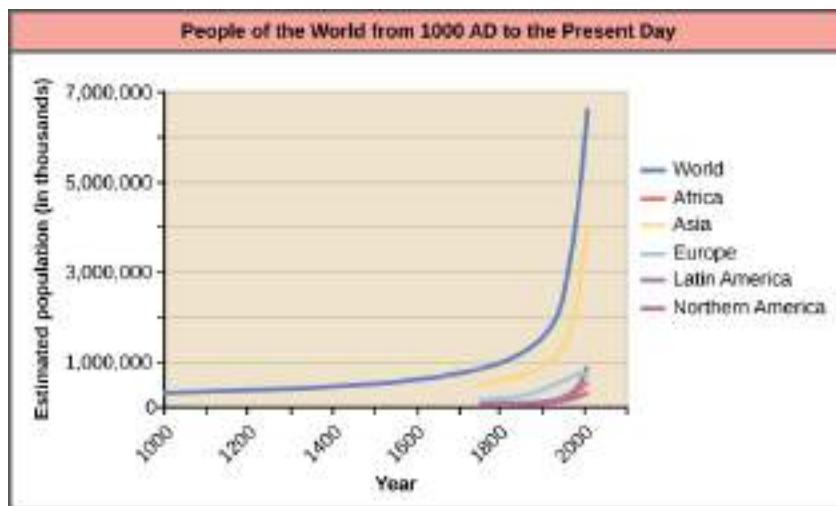

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

Concepts of animal population dynamics can be applied to human population growth. Humans are not unique in their ability to alter their environment. For example, beaver dams alter the stream environment where they are built. Humans, however, have the ability to alter their environment to increase its carrying capacity sometimes to the detriment of other species (e.g., via artificial selection for crops that have a higher yield). Earth's human population is growing rapidly, to the extent that some worry about the ability of the earth's environment to sustain this population, as long-term exponential growth carries the potential risks of famine, disease, and large-scale death.

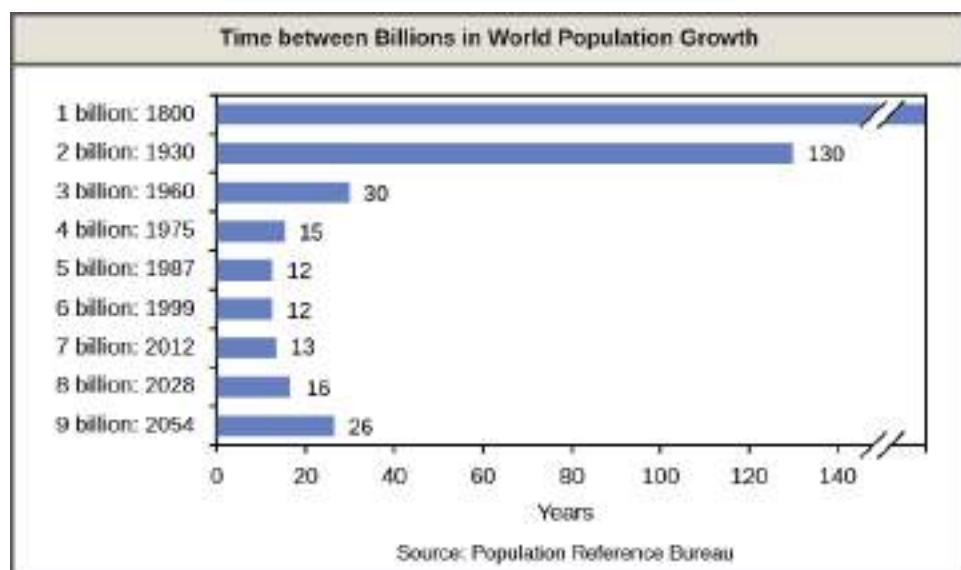

Although humans have increased the carrying capacity of their environment, the technologies used to achieve this transformation have caused unprecedented changes to Earth's environment, altering ecosystems to the point where some may be in danger of collapse. The depletion of the ozone layer, erosion due to acid rain, and damage from global climate change are caused by human activities. The ultimate effect of these changes on our carrying capacity is unknown. As some point out, it is likely that the negative effects of increasing carrying capacity will outweigh the positive ones—the carrying capacity of the world for human beings might actually decrease.

The world's human population is currently experiencing exponential growth even though human reproduction is far below its biotic potential (**Figure 36.15**). To reach its biotic potential, all females would have to become pregnant every nine months or so during their reproductive years. Also, resources would have to be such that the environment would support such growth. Neither of these two conditions exists. In spite of this fact, human population is still growing exponentially.

**Figure 36.15** Human population growth since 1000 AD is exponential (dark blue line). Notice that while the population in Asia (yellow line), which has many economically underdeveloped countries, is increasing exponentially, the population in Europe (light blue line), where most of the countries are economically developed, is growing much more slowly.

A consequence of exponential human population growth is the time that it takes to add a particular number of humans to the Earth is becoming shorter. **Figure 36.16** shows that 123 years were necessary to add 1 billion humans in 1930, but it only took 24 years to add two billion people between 1975 and 1999. As already discussed, at some point it would appear that our ability to increase our carrying capacity indefinitely on a finite world is uncertain. Without new technological advances, the human growth rate has been predicted to slow in the coming decades. However, the population will still be increasing and the threat of overpopulation remains.

**Figure 36.16** The time between the addition of each billion human beings to Earth decreases over time. (credit: modification of work by Ryan T. Cragun)

Click through this **interactive view** ([http://openstaxcollege.org/l/human\\_growth](http://openstaxcollege.org/l/human_growth)) of how human populations have changed over time.

Based on the interactive, how would you describe human population growth?

- a. a decline in human population growth
- b. a lag in human population growth
- c. logistic growth
- d. exponential growth

## Overcoming Density-Dependent Regulation

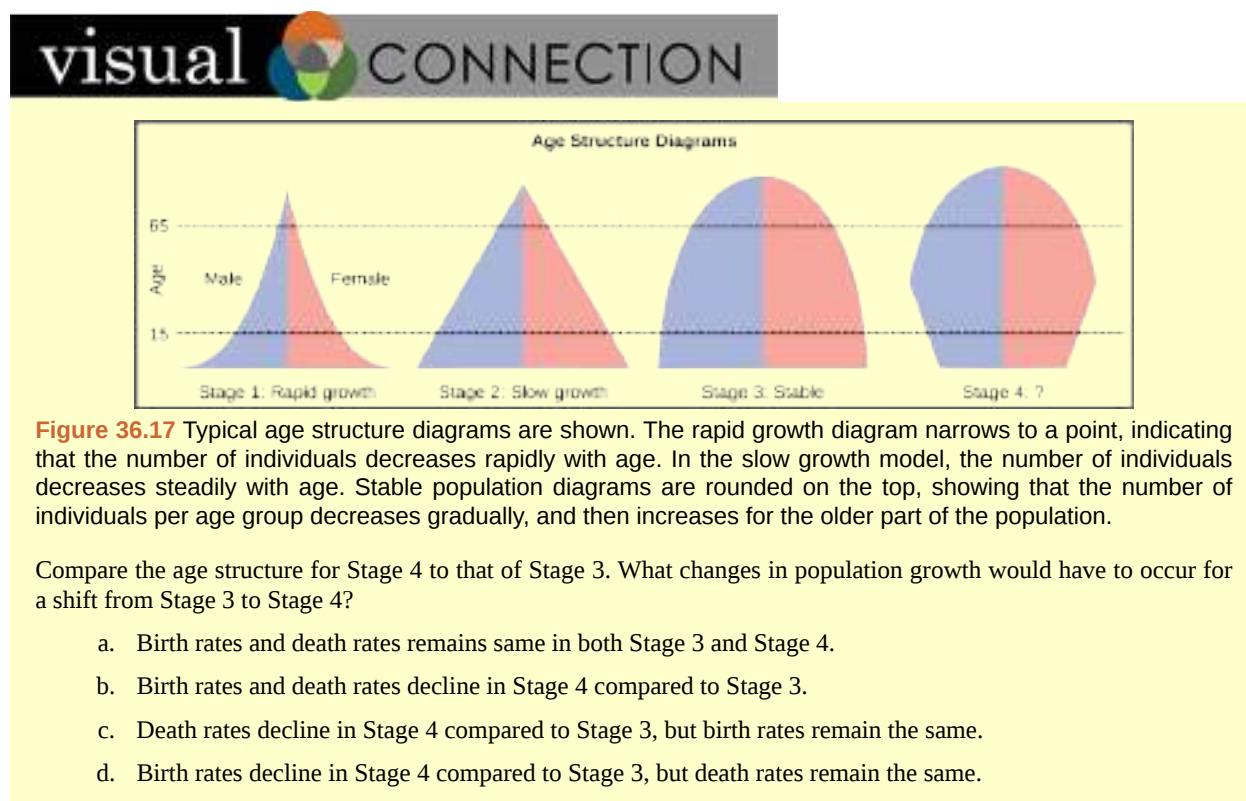

Humans are unique in their ability to alter their environment with the conscious purpose of increasing its carrying capacity. This ability is a major factor responsible for human population growth and a way of overcoming density-dependent growth regulation. Much of this ability is related to human intelligence, society, and communication. Humans can construct shelter to protect them from the elements and have developed agriculture and domesticated animals to increase their food supplies. In addition, humans use language to communicate this technology to new generations, allowing them to improve upon previous accomplishments.

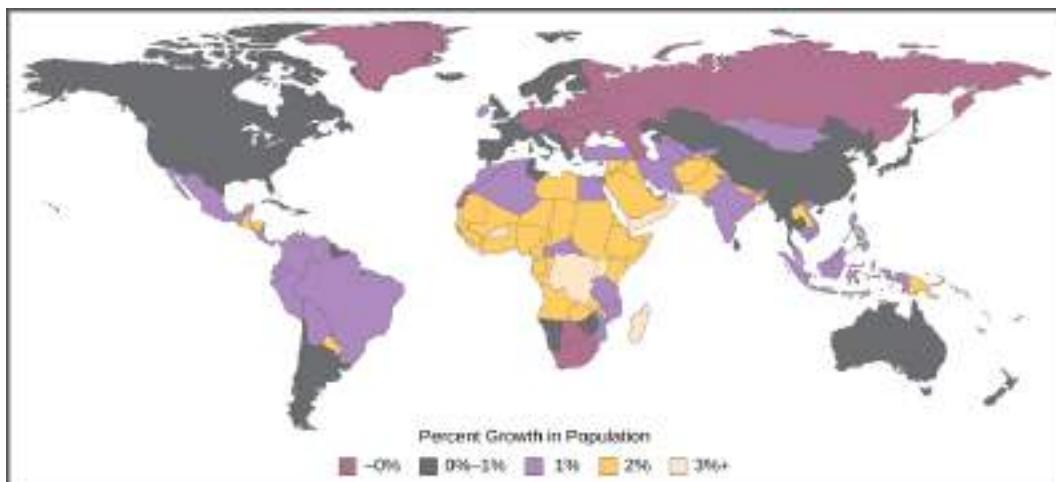

Other factors in human population growth are migration and public health. Humans originated in Africa, but have since migrated to nearly all inhabitable land on the Earth. Public health, sanitation, and the use of antibiotics and vaccines have decreased the ability of infectious disease to limit human population growth. In the past, diseases such as the bubonic plague of the fourteenth century killed between 30 and 60 percent of Europe's population and reduced the overall world population by as many as 100 million people. Today, the threat of infectious disease, while not gone, is certainly less severe. According to the World Health Organization, global death from infectious disease declined from 16.4 million in 1993 to 14.7 million in 2002. To compare to some of the epidemics of the past, the percentage of the world's population killed between 1993 and

2002 decreased from 0.30 percent of the world's population to 0.24 percent. Thus, it appears that the influence of infectious disease on human population growth is becoming less significant.

## Age Structure, Population Growth, and Economic Development

The age structure of a population is an important factor in population dynamics. **Age structure** is the proportion of a population at different age ranges. Age structure allows better prediction of population growth, plus the ability to associate this growth with the level of economic development in the region. Countries with rapid growth have a pyramidal shape in their age structure diagrams, showing a preponderance of younger individuals, many of whom are of reproductive age or will be soon ([Figure 36.17](#)). This pattern is most often observed in underdeveloped countries where individuals do not live to old age because of less-than-optimal living conditions. Age structures of areas with slow growth, including developed countries such as the United States, still have a pyramidal structure, but with many fewer young and reproductive-aged individuals and a greater proportion of older individuals. Other developed countries, such as Italy, have zero population growth. The age structure of these populations is more conical, with an even greater percentage of middle-aged and older individuals. The actual growth rates in different countries are shown in [Figure 36.18](#), with the highest rates tending to be in the less economically developed countries of Africa and Asia.

**Figure 36.18** The percent growth rate of population in different countries is shown. Notice that the highest growth is occurring in less economically developed countries in Africa and Asia.

## Long-Term Consequences of Exponential Human Population Growth

Many dire predictions have been made about the world's population leading to a major crisis called the "population explosion." In the 1968 book *The Population Bomb*, biologist Dr. Paul R. Ehrlich wrote, "The battle to feed all of humanity is over. In the 1970s hundreds of millions of people will starve to death in spite of any crash programs embarked upon now. At this late date nothing can prevent a substantial increase in the world death rate."<sup>8</sup> While many critics view this statement as an exaggeration, the laws of exponential population growth are still in effect, and unchecked human population growth cannot continue indefinitely.

Efforts to control population growth led to the **one-child policy** in China, which used to include more severe consequences, but now imposes fines on urban couples who have more than one child. Due to the fact that some couples wish to have a male heir, many Chinese couples continue to have more than one child. The policy itself, its social impacts, and the effectiveness of limiting overall population growth are controversial. In spite of population control policies, the human population continues to grow. At some point the food supply may run out because of the subsequent need to produce more and more food to feed our population. The United Nations estimates that future world population growth may vary from 6 billion (a decrease) to 16 billion people by the year 2100. There is no way to know whether human population growth will moderate to the point where the crisis described by Dr. Ehrlich will be averted.

Another result of population growth is the endangerment of the natural environment. Many countries have attempted to reduce the human impact on climate change by reducing their emission of the greenhouse gas carbon dioxide. However, these treaties have not been ratified by every country, and many underdeveloped countries trying to improve their economic condition may be less likely to agree with such provisions if it means slower economic development. Furthermore, the role of human activity in causing climate change has become a hotly debated socio-political issue in some developed countries, including the United States. Thus, we enter the future with considerable uncertainty about our ability to curb human population growth and protect our environment.

Visit this [website](http://openstaxcollege.org/l/populations) (<http://openstaxcollege.org/l/populations>) and select “Launch movie” for an animation discussing the global impacts of human population growth.

## Section Summary

The world’s human population is growing at an exponential rate. Humans have increased the world’s carrying capacity through migration, agriculture, medical advances, and communication. The age structure of a population allows us to predict population growth. Unchecked human population growth could have dire long-term effects on our environment.

## 36.6 | Community Ecology

In this section, you will explore the following questions:

- What is the predator-prey cycle?
- What are examples of defenses against predation and herbivory?
- What is the competitive exclusion principle?
- What are examples of symbiotic relationship among species?
- What is community structure and succession?

## Connection for AP<sup>®</sup> Courses

Topics explored in this section that are in scope for AP<sup>®</sup> include mimicry, the competitive exclusion principle, symbiosis, keystone and foundation species, and primary and secondary succession. Species interact in many ways, the classical example of species interaction being the hunting of prey by its predator. In most cases, populations of predators and prey vary in cycles. Beyond predation, because resources are often limited in an environment, multiple species may compete to obtain them. Communities are complex entities defined by the types and number of species and the dynamics of how they change over time. Like populations, communities change in structure and composition, often by environmental disturbances such as fire or hurricanes.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 and Big Idea 4 of the AP<sup>®</sup> Biology Curriculum Framework. The learning objectives listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

Populations rarely, if ever, live in isolation from populations of other species. In most cases, numerous species share a habitat. The interactions between these populations play a major role in regulating population growth and abundance. All populations occupying the same habitat form a community: populations inhabiting a specific area at the same time. The number of species occupying the same habitat and their relative abundance is known as species diversity. Areas with low diversity, such as the glaciers of Antarctica, still contain a wide variety of living things, whereas the diversity of tropical rainforests is so great that it cannot be counted. Ecology is studied at the community level to understand how species interact with each other and compete for the same resources.

## Predation and Herbivory

Perhaps the classical example of species interaction is predation: the hunting of prey by its predator. Nature shows on television highlight the drama of one living organism killing another. Populations of predators and prey in a community are not constant over time: in most cases, they vary in cycles that appear to be related. The most often cited example of predator-prey dynamics is seen in the cycling of the lynx (predator) and the snowshoe hare (prey), using nearly 200 year-old trapping data from North American forests (Figure 36.19). This cycle of predator and prey lasts approximately 10 years, with the predator population lagging 1–2 years behind that of the prey population. As the hare numbers increase, there is more food available for the lynx, allowing the lynx population to increase as well. When the lynx population grows to a threshold level, however, they kill so many hares that hare population begins to decline, followed by a decline in the lynx population because of scarcity of food. When the lynx population is low, the hare population size begins to increase due, at least in part, to low predation pressure, starting the cycle anew.

**Figure 36.19** The cycling of lynx and snowshoe hare populations in Northern Ontario is an example of predator-prey dynamics.

The idea that the population cycling of the two species is entirely controlled by predation models has come under question. More recent studies have pointed to undefined density-dependent factors as being important in the cycling, in addition to predation. One possibility is that the cycling is inherent in the hare population due to density-dependent effects such as lower fecundity (maternal stress) caused by crowding when the hare population gets too dense. The hare cycling would then induce the cycling of the lynx because it is the lynxes' major food source. The more we study communities, the more complexities we find, allowing ecologists to derive more accurate and sophisticated models of population dynamics.

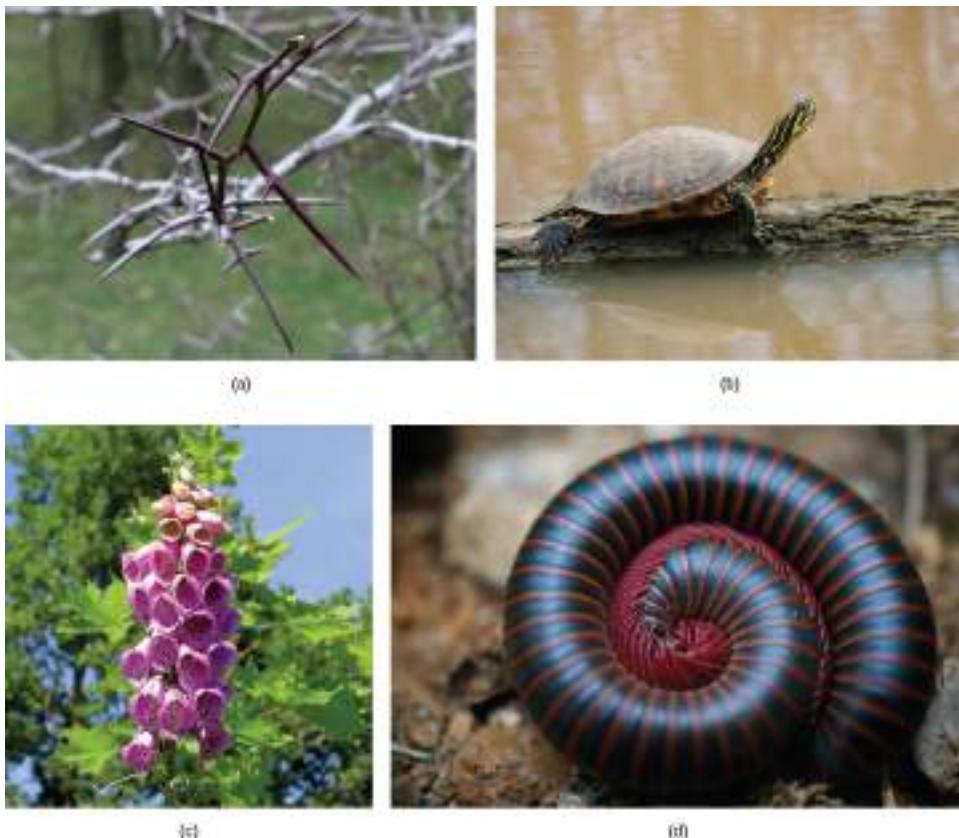

Herbivory describes the consumption of plants by insects and other animals, and it is another interspecific relationship that affects populations. Unlike animals, most plants cannot outrun predators or use mimicry to hide from hungry animals. Some

plants have developed mechanisms to defend against herbivory. Other species have developed mutualistic relationships; for example, herbivory provides a mechanism of seed distribution that aids in plant reproduction.

### Defense Mechanisms against Predation and Herbivory

The study of communities must consider evolutionary forces that act on the members of the various populations contained within it. Species are not static, but slowly changing and adapting to their environment by natural selection and other evolutionary forces. Species have evolved numerous mechanisms to escape predation and herbivory. These defenses may be mechanical, chemical, physical, or behavioral.

Mechanical defenses, such as the presence of thorns on plants or the hard shell on turtles, discourage animal predation and herbivory by causing physical pain to the predator or by physically preventing the predator from being able to eat the prey. Chemical defenses are produced by many animals as well as plants, such as the foxglove which is extremely toxic when eaten. **Figure 36.20** shows some organisms' defenses against predation and herbivory.

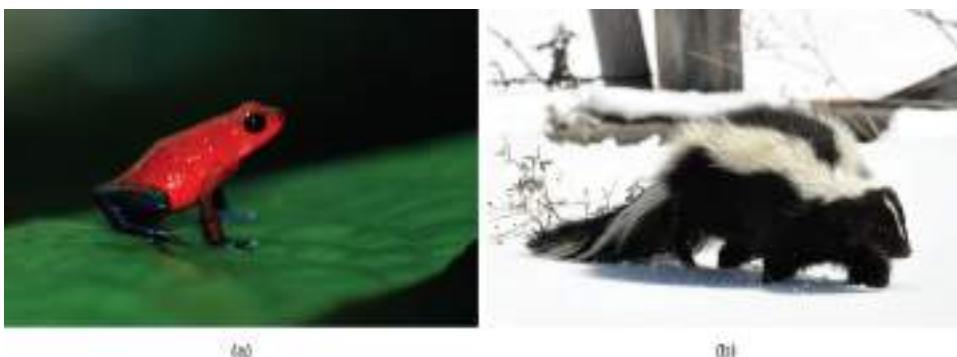

**Figure 36.20** The (a) honey locust tree (*Gleditsia triacanthos*) uses thorns, a mechanical defense, against herbivores, while the (b) Florida red-bellied turtle (*Pseudemys nelsoni*) uses its shell as a mechanical defense against predators. (c) Foxglove (*Digitalis* sp.) uses a chemical defense: toxins produced by the plant can cause nausea, vomiting, hallucinations, convulsions, or death when consumed. (d) The North American millipede (*Narceus americanus*) uses both mechanical and chemical defenses: when threatened, the millipede curls into a defensive ball and produces a noxious substance that irritates eyes and skin. (credit a: modification of work by Huw Williams; credit b: modification of work by "JamieS93"/Flickr; credit c: modification of work by Philip Jägenstedt; credit d: modification of work by Cory Zanker)

Many species use their body shape and coloration to avoid being detected by predators. The tropical walking stick is an insect with the coloration and body shape of a twig which makes it very hard to see when stationary against a background of real twigs (**Figure 36.21a**). In another example, the chameleon can change its color to match its surroundings (**Figure 36.21b**). Both of these are examples of **camouflage**, or avoiding detection by blending in with the background.

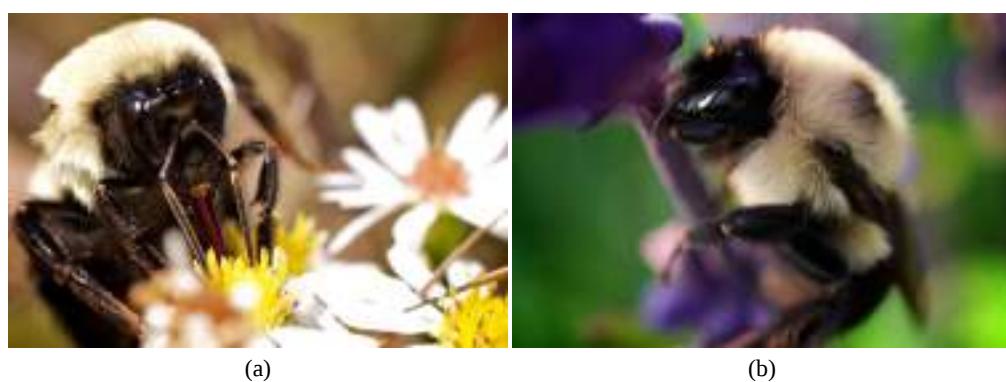

**Figure 36.21** (a) The tropical walking stick and (b) the chameleon use body shape and/or coloration to prevent detection by predators. (credit a: modification of work by Linda Tanner; credit b: modification of work by Frank Vassen)

Some species use coloration as a way of warning predators that they are not good to eat. For example, the cinnabar moth caterpillar, the fire-bellied toad, and many species of beetle have bright colors that warn of a foul taste, the presence of toxic chemical, and/or the ability to sting or bite, respectively. Predators that ignore this coloration and eat the organisms will experience their unpleasant taste or presence of toxic chemicals and learn not to eat them in the future. This type of defensive mechanism is called **aposematic coloration**, or warning coloration (Figure 36.22).

**Figure 36.22** (a) The strawberry poison dart frog (*Oophaga pumilio*) uses aposematic coloration to warn predators that it is toxic, while the (b) striped skunk (*Mephitis mephitis*) uses aposematic coloration to warn predators of the unpleasant odor it produces. (credit a: modification of work by Jay Iwasaki; credit b: modification of work by Dan Dzurisin)

While some predators learn to avoid eating certain potential prey because of their coloration, other species have evolved mechanisms to mimic this coloration to avoid being eaten, even though they themselves may not be unpleasant to eat or contain toxic chemicals. In **Batesian mimicry**, a harmless species imitates the warning coloration of a harmful one. Assuming they share the same predators, this coloration then protects the harmless ones, even though they do not have the same level of physical or chemical defenses against predation as the organism they mimic. Many insect species mimic the coloration of wasps or bees, which are stinging, venomous insects, thereby discouraging predation (Figure 36.23).

**Figure 36.23** Batesian mimicry occurs when a harmless species mimics the coloration of a harmful species, as is seen with the (a) bumblebee and (b) bee-like robber fly. (credit a, b: modification of work by Cory Zanker)

In **Müllerian mimicry**, multiple species share the same warning coloration, but all of them actually have defenses. **Figure 36.24** shows a variety of foul-tasting butterflies with similar coloration. In **Emsleyan/Mertensian mimicry**, a deadly prey mimics a less dangerous one, such as the venomous coral snake mimicking the non-venomous milk snake. This type of mimicry is extremely rare and more difficult to understand than the previous two types. For this type of mimicry to work, it is essential that eating the milk snake has unpleasant but not fatal consequences. Then, these predators learn not to eat snakes with this coloration, protecting the coral snake as well. If the snake were fatal to the predator, there would be no opportunity for the predator to learn not to eat it, and the benefit for the less toxic species would disappear.

**Figure 36.24** Several unpleasant-tasting *Heliconius* butterfly species share a similar color pattern with better-tasting varieties, an example of Müllerian mimicry. (credit: Joron M, Papa R, Beltrán M, Chamberlain N, Mavárez J, et al.)

Go to this **website** ([http://openstaxcollege.org/l/find\\_the\\_mimic](http://openstaxcollege.org/l/find_the_mimic)) to view stunning examples of mimicry.

Explain the most important reason why mimicry and camouflage are so important in the animal world.

- a. Mimicry and camouflage are adaptations that give these animals a advantage in finding prey over others that do not have these adaptations.
- b. Mimicry and camouflage are adaptations that give these animals a survival advantage over others that do not have these adaptations.
- c. Mimicry and camouflage are aposematic defense mechanisms that give these animals a survival advantage over others that do not have these mechanisms.
- d. Mimicry and camouflage are aposematic defense mechanisms that give these animals a reproductive advantage over others that do not have these mechanisms.

## Competitive Exclusion Principle

Resources are often limited within a habitat and multiple species may compete to obtain them. All species have an ecological niche in the ecosystem, which describes how they acquire the resources they need and how they interact with other species in the community. The **competitive exclusion principle** states that two species cannot occupy the same niche in a habitat. In other words, different species cannot coexist in a community if they are competing for all the same resources. An example of this principle is shown in **Figure 36.25**, with two protozoan species, *Paramecium aurelia* and *Paramecium caudatum*. When grown individually in the laboratory, they both thrive. But when they are placed together in the same test tube (habitat), *P. aurelia* outcompetes *P. caudatum* for food, leading to the latter's eventual extinction.

**Figure 36.25** *Paramecium aurelia* and *Paramecium caudatum* grow well individually, but when they compete for the same resources, the *P. aurelia* outcompetes the *P. caudatum*.

This exclusion may be avoided if a population evolves to make use of a different resource, a different area of the habitat, or feeds during a different time of day, called resource partitioning. The two organisms are then said to occupy different microniches. These organisms coexist by minimizing direct competition.

## Symbiosis

Symbiotic relationships, or **symbioses** (plural), are close interactions between individuals of different species over an extended period of time which impact the abundance and distribution of the associating populations. Most scientists accept this definition, but some restrict the term to only those species that are mutualistic, where both individuals benefit from the interaction. In this discussion, the broader definition will be used.

### Commensalism

A **commensal** relationship occurs when one species benefits from the close, prolonged interaction, while the other neither benefits nor is harmed. Birds nesting in trees provide an example of a commensal relationship (**Figure 36.26**). The tree is not harmed by the presence of the nest among its branches. The nests are light and produce little strain on the structural integrity of the branch, and most of the leaves, which the tree uses to get energy by photosynthesis, are above the nest so they are unaffected. The bird, on the other hand, benefits greatly. If the bird had to nest in the open, its eggs and young would be vulnerable to predators. Another example of a commensal relationship is the clown fish and the sea anemone. The sea anemone is not harmed by the fish, and the fish benefits with protection from predators who would be stung upon nearing the sea anemone.

**Figure 36.26** The southern masked-weaver bird is starting to make a nest in a tree in Zambezi Valley, Zambia. This is an example of a commensal relationship, in which one species (the bird) benefits, while the other (the tree) neither benefits nor is harmed. (credit: "Hanay"/Wikimedia Commons)

### Mutualism

A second type of symbiotic relationship is called **mutualism**, where two species benefit from their interaction. Some scientists believe that these are the only true examples of symbiosis. For example, termites have a mutualistic relationship with protozoa that live in the insect's gut (Figure 36.27a). The termite benefits from the ability of bacterial symbionts within the protozoa to digest cellulose. The termite itself cannot do this, and without the protozoa, it would not be able to obtain energy from its food (cellulose from the wood it chews and eats). The protozoa and the bacterial symbionts benefit by having a protective environment and a constant supply of food from the wood chewing actions of the termite. Lichens have a mutualistic relationship between fungus and photosynthetic algae or bacteria (Figure 36.27b). As these symbionts grow together, the glucose produced by the algae provides nourishment for both organisms, whereas the physical structure of the lichen protects the algae from the elements and makes certain nutrients in the atmosphere more available to the algae.

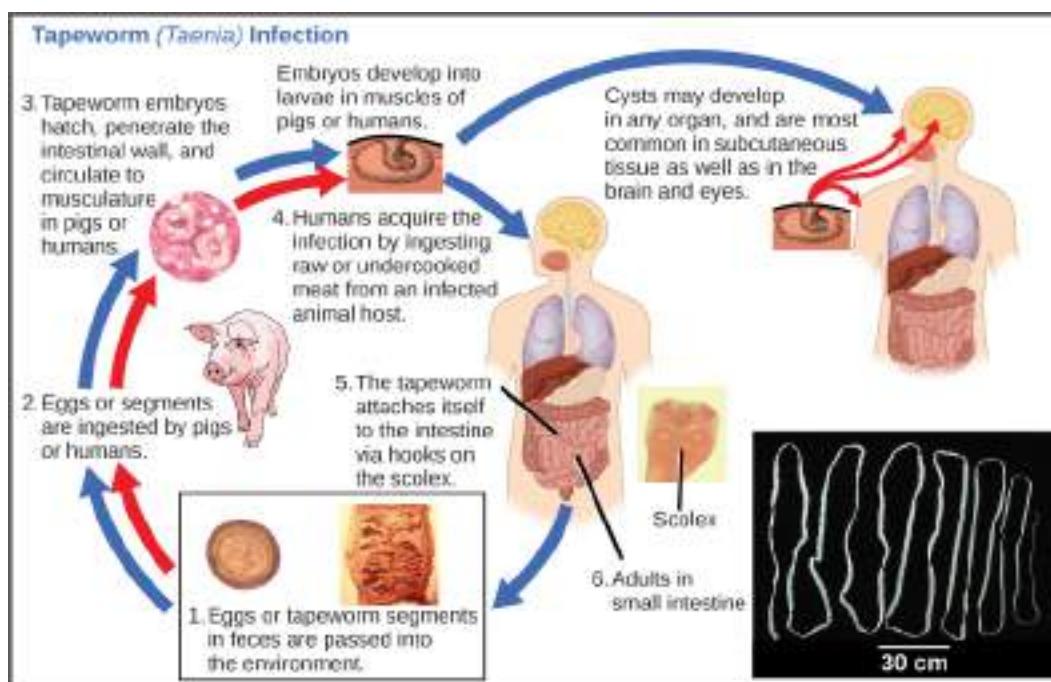

**Figure 36.27** (a) Termites form a mutualistic relationship with symbiotic protozoa in their guts, which allow both organisms to obtain energy from the cellulose the termite consumes. (b) Lichen is a fungus that has symbiotic photosynthetic algae living inside its cells. (credit a: modification of work by Scott Bauer, USDA; credit b: modification of work by Cory Zanker)

### Parasitism

A **parasite** is an organism that lives in or on another living organism and derives nutrients from it. In this relationship, the parasite benefits, but the organism being fed upon, the **host** is harmed. The host is usually weakened by the parasite as it siphons resources the host would normally use to maintain itself. The parasite, however, is unlikely to kill the host, especially not quickly, because this would allow no time for the organism to complete its reproductive cycle by spreading to another host.

The reproductive cycles of parasites are often very complex, sometimes requiring more than one host species. A tapeworm is a parasite that causes disease in humans when contaminated, undercooked meat such as pork, fish, or beef is consumed (Figure 36.28). The tapeworm can live inside the intestine of the host for several years, benefiting from the food the host

is bringing into its gut by eating, and may grow to be over 50 ft long by adding segments. The parasite moves from species to species in a cycle, making two hosts necessary to complete its life cycle. Another common parasite is *Plasmodium falciparum*, the protozoan cause of malaria, a significant disease in many parts of the world. Living in human liver and red blood cells, the organism reproduces asexually in the gut of blood-feeding mosquitoes to complete its life cycle. Thus malaria is spread from human to human by mosquitoes, one of many arthropod-borne infectious diseases.

**Figure 36.28** This diagram shows the life cycle of a pork tapeworm (*Taenia solium*), a human worm parasite. (credit: modification of work by CDC)

## Characteristics of Communities

Communities are complex entities that can be characterized by their structure (the types and numbers of species present) and dynamics (how communities change over time). Understanding community structure and dynamics enables community ecologists to manage ecosystems more effectively.

### Foundation Species

**Foundation species** are considered the “base” or “bedrock” of a community, having the greatest influence on its overall structure. They are usually the primary producers: organisms that bring most of the energy into the community. Kelp, brown algae, is a foundation species, forming the basis of the kelp forests off the coast of California.

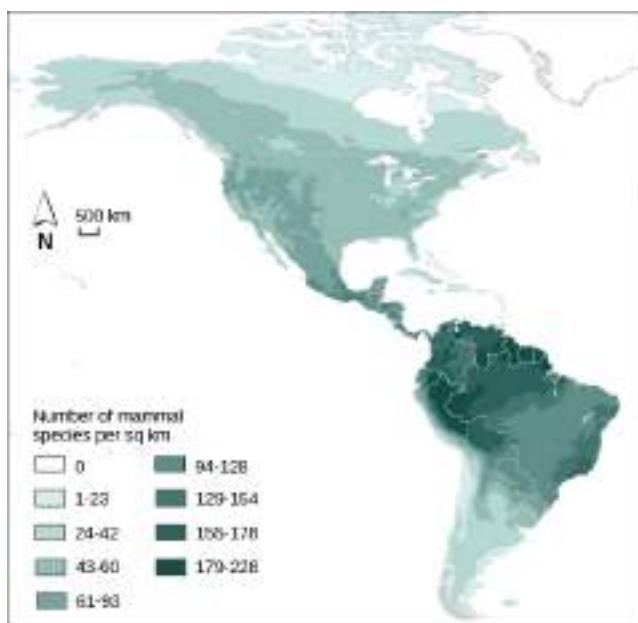

Foundation species may physically modify the environment to produce and maintain habitats that benefit the other organisms that use them. An example is the photosynthetic corals of the coral reef (Figure 36.29). Corals themselves are not photosynthetic, but harbor symbionts within their body tissues (dinoflagellates called zooxanthellae) that perform photosynthesis; this is another example of a mutualism. The exoskeletons of living and dead coral make up most of the reef structure, which protects many other species from waves and ocean currents.

**Figure 36.29** Coral is the foundation species of coral reef ecosystems. (credit: Jim E. Maragos, USFWS)

### Biodiversity, Species Richness, and Relative Species Abundance

Biodiversity describes a community's biological complexity: it is measured by the number of different species (species richness) in a particular area and their relative abundance (species evenness). The area in question could be a habitat, a biome, or the entire biosphere. **Species richness** is the term that is used to describe the number of species living in a habitat or biome. Species richness varies across the globe (Figure 36.30). One factor in determining species richness is latitude, with the greatest species richness occurring in ecosystems near the equator, which often have warmer temperatures, large amounts of rainfall, and low seasonality. The lowest species richness occurs near the poles, which are much colder, drier, and thus less conducive to life in Geologic time (time since glaciations). The predictability of climate or productivity is also an important factor. Other factors influence species richness as well. For example, the study of **island biogeography** attempts to explain the relatively high species richness found in certain isolated island chains, including the Galápagos Islands that inspired the young Darwin. **Relative species abundance** is the number of individuals in a species relative to the total number of individuals in all species within a habitat, ecosystem, or biome. Foundation species often have the highest relative abundance of species.

**Figure 36.30** The greatest species richness for mammals in North and South America is associated with the equatorial latitudes. (credit: modification of work by NASA, CIESIN, Columbia University)

### Keystone Species

A **keystone species** is one whose presence is key to maintaining biodiversity within an ecosystem and to upholding an ecological community's structure. The intertidal sea star, *Pisaster ochraceus*, of the northwestern United States is a keystone species (Figure 36.31). Studies have shown that when this organism is removed from communities, populations of their natural prey (mussels) increase, completely altering the species composition and reducing biodiversity. Another keystone species is the banded tetra, a fish in tropical streams, which supplies nearly all of the phosphorus, a necessary inorganic nutrient, to the rest of the community. If these fish were to become extinct, the community would be greatly affected.

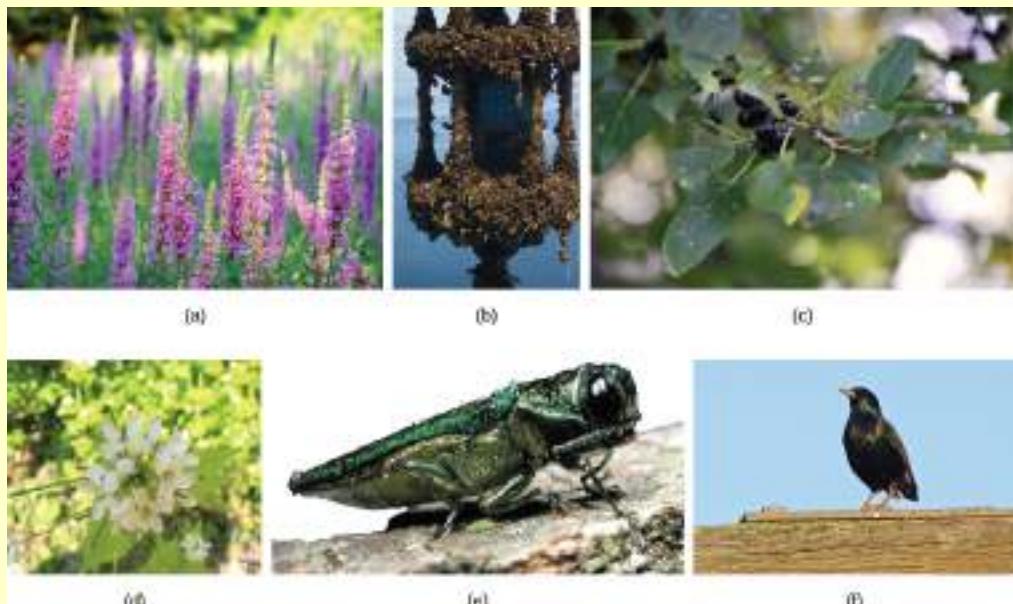

**Figure 36.31** The *Pisaster ochraceus* sea star is a keystone species. (credit: Jerry Kirkhart)

# everyday CONNECTION

## Invasive Species

Invasive species are non-native organisms that, when introduced to an area out of their native range, threaten the ecosystem balance of that habitat. Many such species exist in the United States, as shown in **Figure 36.32**. Whether enjoying a forest hike, taking a summer boat trip, or simply walking down an urban street, you have likely encountered an invasive species.

**Figure 36.32** In the United States, invasive species like (a) purple loosestrife (*Lythrum salicaria*) and the (b) zebra mussel (*Dreissena polymorpha*) threaten certain aquatic ecosystems. Some forests are threatened by the spread of (c) common buckthorn (*Rhamnus cathartica*), (d) garlic mustard (*Alliaria petiolata*), and (e) the emerald ash borer (*Agrilus planipennis*). The (f) European starling (*Sturnus vulgaris*) may compete with native bird species for nest holes. (credit a: modification of work by Liz West; credit b: modification of work by M. McCormick, NOAA; credit c: modification of work by E. Dronkert; credit d: modification of work by Dan Davison; credit e: modification of work by USDA; credit f: modification of work by Don DeBold)

One of the many recent proliferations of an invasive species concerns the growth of Asian carp populations. Asian carp were introduced to the United States in the 1970s by fisheries and sewage treatment facilities that used the fish's excellent filter feeding capabilities to clean their ponds of excess plankton. Some of the fish escaped, however, and by the 1980s they had colonized many waterways of the Mississippi River basin, including the Illinois and Missouri Rivers.

Voracious eaters and rapid reproducers, Asian carp may outcompete native species for food, potentially leading to their extinction. For example, black carp are voracious eaters of native mussels and snails, limiting this food source for native fish species. Silver carp eat plankton that native mussels and snails feed on, reducing this food source by a different alteration of the food web. In some areas of the Mississippi River, Asian carp species have become the most predominant, effectively outcompeting native fishes for habitat. In some parts of the Illinois River, Asian carp constitute 95 percent of the community's biomass. Although edible, the fish is bony and not a desired food in the United States. Moreover, their presence threatens the native fish and fisheries of the Great Lakes, which are important to local economies and recreational anglers. Asian carp have even injured humans. The fish, frightened by the sound of approaching motorboats, thrust themselves into the air, often landing in the boat or directly hitting the boaters.

The Great Lakes and their prized salmon and lake trout fisheries are also being threatened by these invasive fish. Asian carp have already colonized rivers and canals that lead into Lake Michigan. One infested waterway of particular importance is the Chicago Sanitary and Ship Channel, the major supply waterway linking the Great Lakes to the Mississippi River. To prevent the Asian carp from leaving the canal, a series of

electric barriers have been successfully used to discourage their migration; however, the threat is significant enough that several states and Canada have sued to have the Chicago channel permanently cut off from Lake Michigan. Local and national politicians have weighed in on how to solve the problem, but no one knows whether the Asian carp will ultimately be considered a nuisance, like other invasive species such as the water hyacinth and zebra mussel, or whether it will be the destroyer of the largest freshwater fishery of the world.

The issues associated with Asian carp show how population and community ecology, fisheries management, and politics intersect on issues of vital importance to the human food supply and economy. Socio-political issues like this make extensive use of the sciences of population ecology (the study of members of a particular species occupying a particular area known as a habitat) and community ecology (the study of the interaction of all species within a habitat).

Why are invasive species such as the Asian carp such a problem in North America?

- a. They release some chemicals into the water which are toxic to the flora and fauna of the freshwater habitats in North America.
- b. They kill the natural fish population native to freshwater habitats in North America by obtaining food from them. The invasive species will then reproduce rapidly.
- c. They provide food and other resources to the native fish population, resulting in an over increase in their population. This decreases the amount of dissolved oxygen in the freshwater habitats of North America.
- d. They are not native to freshwater habitats in North America and have no natural predators to keep their population in check. As a result, they will reproduce rapidly competing with native fish for space, food, and other resources.

## Community Dynamics

Community dynamics are the changes in community structure and composition over time. Sometimes these changes are induced by **environmental disturbances** such as volcanoes, earthquakes, storms, fires, and climate change. Communities with a stable structure are said to be at equilibrium. Following a disturbance, the community may or may not return to the equilibrium state.

Succession describes the sequential appearance and disappearance of species in a community over time. In **primary succession**, newly exposed or newly formed land is colonized by living things; in **secondary succession**, part of an ecosystem is disturbed and remnants of the previous community remain.

### **Primary Succession and Pioneer Species**

Primary succession occurs when new land is formed or rock is exposed: for example, following the eruption of volcanoes, such as those on the Big Island of Hawaii. As lava flows into the ocean, new land is continually being formed. On the Big Island, approximately 32 acres of land is added each year. First, weathering and other natural forces break down the substrate enough for the establishment of certain hearty plants and lichens with few soil requirements, known as **pioneer species** (**Figure 36.33**). These species help to further break down the mineral rich lava into soil where other, less hardy species will grow and eventually replace the pioneer species. In addition, as these early species grow and die, they add to an ever-growing layer of decomposing organic material and contribute to soil formation. Over time the area will reach an equilibrium state, with a set of organisms quite different from the pioneer species.

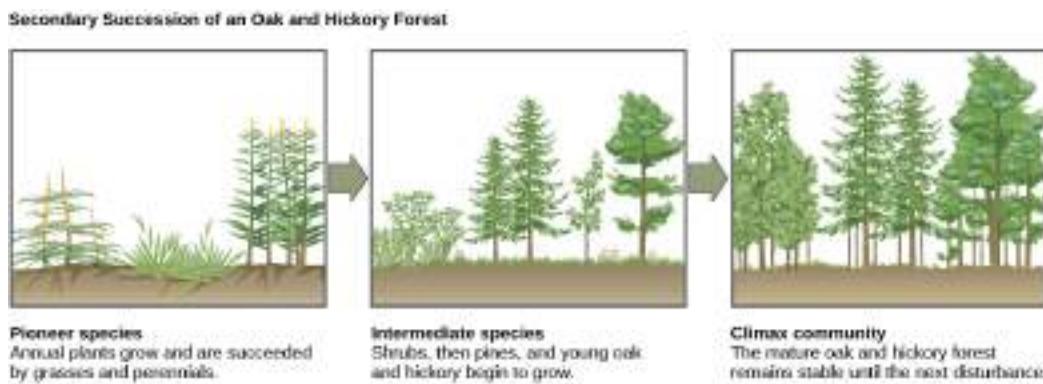

**Figure 36.33** During primary succession in lava on Maui, Hawaii, succulent plants are the pioneer species. (credit: Forest and Kim Starr)

### Secondary Succession

A classic example of secondary succession occurs in oak and hickory forests cleared by wildfire (**Figure 36.34**). Wildfires will burn most vegetation and kill those animals unable to flee the area. Their nutrients, however, are returned to the ground in the form of ash. Thus, even when areas are devoid of life due to severe fires, the area will soon be ready for new life to take hold.

Before the fire, the vegetation was dominated by tall trees with access to the major plant energy resource: sunlight. Their height gave them access to sunlight while also shading the ground and other low-lying species. After the fire, though, these trees are no longer dominant. Thus, the first plants to grow back are usually annual plants followed within a few years by quickly growing and spreading grasses and other pioneer species. Due to, at least in part, changes in the environment brought on by the growth of the grasses and other species, over many years, shrubs will emerge along with small pine, oak, and hickory trees. These organisms are called intermediate species. Eventually, over 150 years, the forest will reach its equilibrium point where species composition is no longer changing and resembles the community before the fire. This equilibrium state is referred to as the **climax community**, which will remain stable until the next disturbance.

**Figure 36.34** Secondary succession is shown in an oak and hickory forest after a forest fire.

### Activity

**Don't Trash the Campus.** Design and implement a plan to investigate the impact of school litter on a surrounding community. Based on collected data, create a proposal of short- and long-term solutions to the trash problem on campus and submit the proposal to the student council for consideration. Describes ways in which communities/ecosystems can recover from modern levels of local environmental disturbances.

## Section Summary

Communities include all the different species living in a given area. The variety of these species is called species richness. Many organisms have developed defenses against predation and herbivory, including mechanical defenses, warning coloration, and mimicry, as a result of evolution and the interaction with other members of the community. Two species cannot exist in the same habitat competing directly for the same resources. Species may form symbiotic relationships such as commensalism or mutualism. Community structure is described by its foundation and keystone species. Communities respond to environmental disturbances by succession (the predictable appearance of different types of plant species) until a stable community structure is established.

## 36.7 | Behavioral Biology: Proximate and Ultimate

### Causes of Behavior

In this section, you will explore the following questions:

- What is the difference between innate and learned behavior?
- How are movement and migration behaviors a result of natural selection?
- What are different ways members of a population communicate with each other?
- What are examples of how species use energy for mating displays and other courtship behaviors?
- What are examples of various mating systems?
- What are different ways that species learn?

### Connection for AP<sup>®</sup> Courses

**Behavior** is the change in activity of an organism in response to a stimulus. **Innate behaviors** have a strong genetic component and are largely independent of environmental influences. In other words, these instinctive behaviors are “hard wired.” Examples of innate behaviors include a human baby grabbing her mother’s finger and the stork using its long beak to forage. **Learned behaviors** result from environmental conditioning and are modified by learning. For example, you likely have learned by now that reading these AP<sup>®</sup> Connections help you digest the information and that studying for a test improves your grade.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 and Big Idea 3 of the AP<sup>®</sup> Biology Curriculum Framework. The AP<sup>®</sup> Learning Objective listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Big Idea 2</b>                 | Biological systems utilize free energy and molecular building blocks to grow, to reproduce, and to maintain dynamic homeostasis. |
| <b>Enduring Understanding 2.C</b> | Organisms use feedback mechanisms to regulate growth and reproduction, and to maintain dynamic homeostasis.                      |
| <b>Essential Knowledge</b>        | <b>2.C.2</b> Organisms respond to changes in their external environments.                                                        |
| <b>Science Practice</b>           | <b>6.4</b> The student can make claims and predictions about natural phenomena based on scientific theories and models.          |
| <b>Learning Objective</b>         | <b>4.13</b> The student is able to predict the effects of a change in the community's populations on the community.              |

|                                   |                                                                                                                                                                                                                         |
|-----------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Enduring Understanding 2.E</b> | Many biological processes involved in growth, reproduction and dynamic homeostasis include temporal regulation and coordination.                                                                                        |
| <b>Essential Knowledge</b>        | <b>2.E.3</b> Timing and coordination of behavior are regulated by various mechanisms and are important in natural selection.                                                                                            |
| <b>Science Practice</b>           | <b>4.1</b> The student can justify the selection of the kind of data needed to answer a particular scientific question.                                                                                                 |
| <b>Learning Objective</b>         | <b>2.21</b> The student is able to justify the selection of the kind of data needed to answer scientific questions about the relevant mechanism that organisms use to respond to changes in their external environment. |
| <b>Essential Knowledge</b>        | <b>2.E.3</b> Timing and coordination of behavior are regulated by various mechanisms and are important in natural selection.                                                                                            |
| <b>Science Practice</b>           | <b>5.1</b> The student can analyze data to identify patterns or relationships.                                                                                                                                          |
| <b>Learning Objective</b>         | <b>2.38</b> The student is able to analyze data to support the claim that responses to information and communication of information affect natural selection.                                                           |
| <b>Essential Knowledge</b>        | <b>2.E.3</b> Timing and coordination of behavior are regulated by various mechanisms and are important in natural selection.                                                                                            |
| <b>Science Practice</b>           | <b>6.1</b> The student can justify claims with evidence.                                                                                                                                                                |
| <b>Learning Objective</b>         | <b>2.39</b> The student is able to justify scientific claims, using evidence, to describe how timing and coordination of behavioral events in organisms are regulated by several mechanisms.                            |
| <b>Essential Knowledge</b>        | <b>2.E.3</b> Timing and coordination of behavior are regulated by various mechanisms and are important in natural selection.                                                                                            |
| <b>Science Practice</b>           | <b>7.2</b> The student can connect concepts in and across domain(s) to generalize or extrapolate in and/or across enduring understandings and/or big ideas.                                                             |
| <b>Learning Objective</b>         | <b>2.40</b> The student is able to connect concepts in and across domain(s) to predict how environmental factors affect response to information and change behavior.                                                    |
| <b>Big Idea 3</b>                 | Living systems store, retrieve, transmit and respond to information essential to life processes.                                                                                                                        |
| <b>Enduring Understanding 3.E</b> | Transmission of information results in changes within and between biological systems.                                                                                                                                   |
| <b>Essential Knowledge</b>        | <b>3.E.1</b> Individuals can act on information and communicate it to others.                                                                                                                                           |
| <b>Science Practice</b>           | <b>5.1</b> The student can analyze data to identify patterns or relationships.                                                                                                                                          |
| <b>Learning Objective</b>         | <b>3.40</b> The student is able to analyze data that indicate how organisms exchange information in response to internal changes and external cues, and which can change behavior.                                      |
| <b>Essential Knowledge</b>        | <b>3.E.1</b> Individuals can act on information and communicate it to others.                                                                                                                                           |
| <b>Science Practice</b>           | <b>1.1</b> The student can create representations and models of natural or man-made phenomena and systems in the domain.                                                                                                |
| <b>Learning Objective</b>         | <b>3.41</b> The student is able to create a representation that describes how organisms exchange information in response to internal changes and external cues, and which can result in changes in behavior.            |

|                            |                                                                                                                                       |
|----------------------------|---------------------------------------------------------------------------------------------------------------------------------------|
| <b>Essential Knowledge</b> | <b>3.E.1</b> Individuals can act on information and communicate it to others.                                                         |
| <b>Science Practice</b>    | <b>7.1</b> The student can connect phenomena and models across spatial and temporal scales.                                           |
| <b>Learning Objective</b>  | <b>3.42</b> The student is able to describe how organisms exchange information in response to internal changes or environmental cues. |

**Behavioral biology** is the study of the biological and evolutionary bases for such changes. The idea that behaviors evolved as a result of the pressures of natural selection is not new. Animal behavior has been studied for decades, by biologists in the science of **ethology**, by psychologists in the science of comparative psychology, and by scientists of many disciplines in the study of neurobiology. Although there is overlap between these disciplines, scientists in these behavioral fields take different approaches. Comparative psychology is an extension of work done in human and behavioral psychology. Ethology is an extension of genetics, evolution, anatomy, physiology, and other biological disciplines. Still, one cannot study behavioral biology without touching on both comparative psychology and ethology.

One goal of behavioral biology is to dissect out the innate behaviors, which have a strong genetic component and are largely independent of environmental influences, from the learned behaviors, which result from environmental conditioning. Innate behavior, or instinct, is important because there is no risk of an incorrect behavior being learned. They are “hard wired” into the system. On the other hand, learned behaviors, although riskier, are flexible, dynamic, and can be altered according to changes in the environment.

## Innate Behaviors: Movement and Migration

Innate or instinctual behaviors rely on response to stimuli. The simplest example of this is a **reflex action**, an involuntary and rapid response to stimulus. To test the “knee-jerk” reflex, a doctor taps the patellar tendon below the kneecap with a rubber hammer. The stimulation of the nerves there leads to the reflex of extending the leg at the knee. This is similar to the reaction of someone who touches a hot stove and instinctually pulls his or her hand away. Even humans, with our great capacity to learn, still exhibit a variety of innate behaviors.

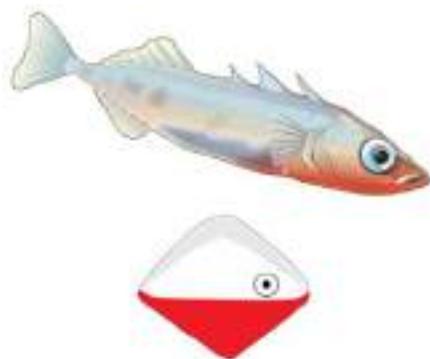

### Kinesis and Taxis

Another activity or movement of innate behavior is **kinesis**, or the undirected movement in response to a stimulus. Orthokinesis is the increased or decreased speed of movement of an organism in response to a stimulus. Woodlice, for example, increase their speed of movement when exposed to high or low temperatures. This movement, although random, increases the probability that the insect spends less time in the unfavorable environment. Another example is klinokinesis, an increase in turning behaviors. It is exhibited by bacteria such as *E. coli* which, in association with orthokinesis, helps the organisms randomly find a more hospitable environment.

A similar, but more directed version of kinesis is **taxis**: the directed movement towards or away from a stimulus. This movement can be in response to light (phototaxis), chemical signals (chemotaxis), or gravity (geotaxis) and can be directed toward (positive) or away (negative) from the source of the stimulus. An example of a positive chemotaxis is exhibited by the unicellular protozoan *Tetrahymena thermophila*. This organism swims using its cilia, at times moving in a straight line, and at other times making turns. The attracting chemotactic agent alters the frequency of turning as the organism moves directly toward the source, following the increasing concentration gradient.

### Fixed Action Patterns

A **fixed action pattern** is a series of movements elicited by a stimulus such that even when the stimulus is removed, the pattern goes on to completion. An example of such a behavior occurs in the three-spined stickleback, a small freshwater fish (**Figure 36.35**). Males of this species develop a red belly during breeding season and show instinctual aggressiveness to other males during this time. In laboratory experiments, researchers exposed such fish to objects that in no way resemble a fish in their shape, but which were painted red on their lower halves. The male sticklebacks responded aggressively to the objects just as if they were real male sticklebacks.

**Figure 36.35** Male three-spined stickleback fish exhibit a fixed action pattern. During mating season, the males, which develop a bright red belly, react strongly to red-bottomed objects that in no way resemble fish.

### Migration

**Migration** is the long-range seasonal movement of animals. It is an evolved, adapted response to variation in resource availability, and it is a common phenomenon found in all major groups of animals. Birds fly south for the winter to get to warmer climates with sufficient food, and salmon migrate to their spawning grounds. The popular 2005 documentary *March of the Penguins* followed the 62-mile migration of emperor penguins through Antarctica to bring food back to their breeding site and to their young. Wildebeests (Figure 36.36) migrate over 1800 miles each year in search of new grasslands.

**Figure 36.36** Wildebeests migrate in a clockwise fashion over 1800 miles each year in search of rain-ripened grass. (credit: Eric Inafuku)

Although migration is thought of as innate behavior, only some migrating species always migrate (obligate migration). Animals that exhibit facultative migration can choose to migrate or not. Additionally, in some animals, only a portion of the population migrates, whereas the rest does not migrate (incomplete migration). For example, owls that live in the tundra may migrate in years when their food source, small rodents, is relatively scarce, but not migrate during the years when rodents are plentiful.

### Foraging

**Foraging** is the act of searching for and exploiting food resources. Feeding behaviors that maximize energy gain and minimize energy expenditure are called optimal foraging behaviors, and these are favored by natural selection. The painted stork, for example, uses its long beak to search the bottom of a freshwater marshland for crabs and other food (Figure 36.37).

**Figure 36.37** The painted stork uses its long beak to forage. (credit: J.M. Garg)

## Innate Behaviors: Living in Groups

Not all animals live in groups, but even those that live relatively solitary lives, with the exception of those that can reproduce asexually, must mate. Mating usually involves one animal signaling another so as to communicate the desire to mate. There are several types of energy-intensive behaviors or displays associated with mating, called mating rituals. Other behaviors found in populations that live in groups are described in terms of which animal benefits from the behavior. In selfish behavior, only the animal in question benefits; in altruistic behavior, one animal's actions benefit another animal; cooperative behavior describes when both animals benefit. All of these behaviors involve some sort of communication between population members.

### Communication within a Species

Animals communicate with each other using stimuli known as **signals**. An example of this is seen in the three-spined stickleback, where the visual signal of a red region in the lower half of a fish signals males to become aggressive and signals females to mate. Other signals are chemical (pheromones), aural (sound), visual (courtship and aggressive displays), or tactile (touch). These types of communication may be instinctual or learned or a combination of both. These are not the same as the communication we associate with language, which has been observed only in humans and perhaps in some species of primates and cetaceans.

A pheromone is a secreted chemical signal used to obtain a response from another individual of the same species. The purpose of pheromones is to elicit a specific behavior from the receiving individual. Pheromones are especially common among social insects, but they are used by many species to attract the opposite sex, to sound alarms, to mark food trails, and to elicit other, more complex behaviors. Even humans are thought to respond to certain pheromones called axillary steroids. These chemicals influence human perception of other people, and in one study were responsible for a group of women synchronizing their menstrual cycles. The role of pheromones in human-to-human communication is still somewhat controversial and continues to be researched.

Songs are an example of an aural signal, one that needs to be heard by the recipient. Perhaps the best known of these are songs of birds, which identify the species and are used to attract mates. Other well-known songs are those of whales, which are of such low frequency that they can travel long distances underwater. Dolphins communicate with each other using a wide variety of vocalizations. Male crickets make chirping sounds using a specialized organ to attract a mate, repel other males, and to announce a successful mating.

**Courtship displays** are a series of ritualized visual behaviors (signals) designed to attract and convince a member of the opposite sex to mate. These displays are ubiquitous in the animal kingdom. Often these displays involve a series of steps, including an initial display by one member followed by a response from the other. If at any point, the display is performed incorrectly or a proper response is not given, the mating ritual is abandoned and the mating attempt will be unsuccessful. The mating display of the common stork is shown in **Figure 36.38**.

**Aggressive displays** are also common in the animal kingdom. An example is when a dog bares its teeth when it wants another dog to back down. Presumably, these displays communicate not only the willingness of the animal to fight, but also its fighting ability. Although these displays do signal aggression on the part of the sender, it is thought that these displays are actually a mechanism to reduce the amount of actual fighting that occurs between members of the same species: they allow individuals to assess the fighting ability of their opponent and thus decide whether it is "worth the fight." The testing of certain hypotheses using game theory has led to the conclusion that some of these displays may overstate an animal's actual fighting ability and are used to "bluff" the opponent. This type of interaction, even if "dishonest," would be favored by natural selection if it is successful more times than not.

**Figure 36.38** This stork's courtship display is designed to attract potential mates. (credit: Linda "jinterwas"/Flickr)

**Distraction displays** are seen in birds and some fish. They are designed to attract a predator away from the nest that contains their young. This is an example of an altruistic behavior: it benefits the young more than the individual performing the display, which is putting itself at risk by doing so.

Many animals, especially primates, communicate with other members in the group through touch. Activities such as grooming, touching the shoulder or root of the tail, embracing, lip contact, and greeting ceremonies have all been observed in the Indian langur, an Old World monkey. Similar behaviors are found in other primates, especially in the great apes.

The killdeer bird distracts predators from its eggs by faking a broken wing display in this **video** ([http://openstaxcollege.org/l/killdeer\\_bird](http://openstaxcollege.org/l/killdeer_bird)) taken in Boise, Idaho.

Explain why the behavior shown in the video represents both a distraction display and an altruistic type of behavior.

- a. The parent creates a distraction to attract the predator away from young fledgling by pretending to have a broken wing. It is an altruistic behavior as the parent runs the risk of getting killed or harmed by predator.
- b. The parent creates a distraction by being more aggressive and showing its willingness to fight. Altruistic behavior is seen as the parent runs the risk of getting attacked, killed, or harmed by the predator.
- c. Parent creates distraction to attract the predator away from young fledgling by pretending to have a broken wing. It is exhibiting an altruistic behavior as in saving its fledgling; it is increasing its own fitness along with the fitness of the young bird.
- d. Parent creates distraction by being more aggressive and showing its willingness to fight. It is exhibiting an altruistic behavior by saving its fledgling; it is decreasing its own fitness along with the fitness of the young bird.

### Altruistic Behaviors

Behaviors that lower the fitness of the individual but increase the fitness of another individual are termed altruistic. Examples of such behaviors are seen widely across the animal kingdom. Social insects such as worker bees have no ability to reproduce, yet they maintain the queen so she can populate the hive with her offspring. Meerkats keep a sentry standing guard to warn the rest of the colony about intruders, even though the sentry is putting itself at risk. Wolves and wild dogs bring meat to pack members not present during a hunt. Lemurs take care of infants unrelated to them. Although on the surface, these behaviors appear to be altruistic, it may not be so simple.

There has been much discussion over why altruistic behaviors exist. Do these behaviors lead to overall evolutionary advantages for their species? Do they help the altruistic individual pass on its own genes? And what about such activities

between unrelated individuals? One explanation for altruistic-type behaviors is found in the genetics of natural selection. In the 1976 book, *The Selfish Gene*, scientist Richard Dawkins attempted to explain many seemingly altruistic behaviors from the viewpoint of the gene itself. Although a gene obviously cannot be selfish in the human sense, it may appear that way if the sacrifice of an individual benefits related individuals that share genes that are identical by descent (present in relatives because of common lineage). Mammal parents make this sacrifice to take care of their offspring. Emperor penguins migrate miles in harsh conditions to bring food back for their young. Selfish gene theory has been controversial over the years and is still discussed among scientists in related fields.

Even less-related individuals, those with less genetic identity than that shared by parent and offspring, benefit from seemingly altruistic behavior. The activities of social insects such as bees, wasps, ants, and termites are good examples. Sterile workers in these societies take care of the queen because they are closely related to it, and as the queen has offspring, she is passing on genes from the workers indirectly. Thus, it is of fitness benefit for the worker to maintain the queen without having any direct chance of passing on its genes due to its sterility. The lowering of individual fitness to enhance the reproductive fitness of a relative and thus one's inclusive fitness evolves through **kin selection**. This phenomenon can explain many superficially altruistic behaviors seen in animals. However, these behaviors may not be truly defined as altruism in these cases because the actor is actually increasing its own fitness either directly (through its own offspring) or indirectly (through the inclusive fitness it gains through relatives that share genes with it).

Unrelated individuals may also act altruistically to each other, and this seems to defy the "selfish gene" explanation. An example of this observed in many monkey species where a monkey will present its back to an unrelated monkey to have that individual pick the parasites from its fur. After a certain amount of time, the roles are reversed and the first monkey now grooms the second monkey. Thus, there is reciprocity in the behavior. Both benefit from the interaction and their fitness is raised more than if neither cooperated nor if one cooperated and the other did not cooperate. This behavior is still not necessarily altruism, as the "giving" behavior of the actor is based on the expectation that it will be the "receiver" of the behavior in the future, termed reciprocal altruism. Reciprocal altruism requires that individuals repeatedly encounter each other, often the result of living in the same social group, and that cheaters (those that never "give back") are punished.

Evolutionary game theory, a modification of classical game theory in mathematics, has shown that many of these so-called "altruistic behaviors" are not altruistic at all. The definition of "pure" altruism, based on human behavior, is an action that benefits another without any direct benefit to oneself. Most of the behaviors previously described do not seem to satisfy this definition, and game theorists are good at finding "selfish" components in them. Others have argued that the terms "selfish" and "altruistic" should be dropped completely when discussing animal behavior, as they describe human behavior and may not be directly applicable to instinctual animal activity. What is clear, though, is that heritable behaviors that improve the chances of passing on one's genes or a portion of one's genes are favored by natural selection and will be retained in future generations as long as those behaviors convey a fitness advantage. These instinctual behaviors may then be applied, in special circumstances, to other species, as long as it doesn't lower the animal's fitness.

### Finding Sex Partners

Not all animals reproduce sexually, but many that do have the same challenge: they need to find a suitable mate and often have to compete with other individuals to obtain one. Significant energy is spent in the process of locating, attracting, and mating with the sex partner. Two types of selection occur during this process and can lead to traits that are important to reproduction called secondary sexual characteristics: **intersexual selection**, the choosing of a mate where individuals of one sex choose mates of the other sex, and **intrasexual selection**, the competition for mates between species members of the same sex. Intersexual selection is often complex because choosing a mate may be based on a variety of visual, aural, tactile, and chemical cues. An example of intersexual selection is when female peacocks choose to mate with the male with the brightest plumage. This type of selection often leads to traits in the chosen sex that do not enhance survival, but are those traits most attractive to the opposite sex (often at the expense of survival). Intrasexual selection involves mating displays and aggressive mating rituals such as rams butting heads—the winner of these battles is the one that is able to mate. Many of these rituals use up considerable energy but result in the selection of the healthiest, strongest, and/or most dominant individuals for mating. Three general mating systems, all involving innate as opposed to learned behaviors, are seen in animal populations: monogamous, polygynous, and polyandrous.

Visit this **website** ([http://openstaxcollege.org/l/sex\\_selection](http://openstaxcollege.org/l/sex_selection)) for informative videos on sexual selection.

The greater sage grouse uses a mating system in which one male mates with many females. Name this mating system.

- a. polyandrous
- b. monogamous
- c. intrasexual selection
- d. polygynous

### Activity

In 1980, John Endler published his investigation into natural selection in Trinidad guppies (*Poecilia reticulata*). Some of these guppies have brighter coloration than others. Endler hypothesized that guppies with less predation have brighter colors due to sexual selection because females prefer more brightly-colored males. He then on to hypothesized that male guppies that experience greater predation become more drab-colored to camouflage themselves from predators.. In addition to a laboratory study, he tested this using a field experiment involving four areas. Area 1 had no guppies while area 2 had guppies but no predators. Area 3 had guppies and a predator (*Crenicichla alta*). Endler introduced guppies from area 3 (which were drab because of predation) to area 1 (which had no guppies). The guppies that were relocated to area 1 developed brighter colors over 2 years (enough for several guppy generations) and eventually resembled the guppies in area 2. Make a diagram showing each of the locations, all of the fish species present at the start, and the fish present at the end. Label the fish as “more conspicuous colors” or “less conspicuous colors.”

### Think About It

Describe how this experiment shows that there is genetic variability in the original population. How do you know that there was genetic variability in the fish taken from area 1? Explain the tradeoff between bright colors that are attractive to female guppies and the risk of predation. What would you expect to happen if you moved fish from area 2 back to area 3? What would you expect to happen in each area if female fish began to prefer larger fish rather than more brightly colored fish?

In **monogamous** systems, one male and one female are paired for at least one breeding season. In some animals, such as the gray wolf, these associations can last much longer, even a lifetime. Several explanations have been proposed for this type of mating system. The “mate-guarding hypothesis” states that males stay with the female to prevent other males from mating with her. This behavior is advantageous in such situations where mates are scarce and difficult to find. Another explanation is the “male-assistance hypothesis,” where males that remain with a female to help guard and rear their young will have more and healthier offspring. Monogamy is observed in many bird populations where, in addition to the parental care from the female, the male is also a major provider of parental care for the chicks. A third explanation for the evolutionary advantages of monogamy is the “female-enforcement hypothesis.” In this scenario, the female ensures that the male does not have other offspring that might compete with her own, so she actively interferes with the male’s signaling to attract other mates.

**Polygynous** mating refers to one male mating with multiple females. In these situations, the female must be responsible for most of the parental care as the single male is not capable of providing care to that many offspring. In resourced-based polygyny, males compete for territories with the best resources, and then mate with females that enter the territory, drawn to its resource richness. The female benefits by mating with a dominant, genetically fit male; however, it is at the cost of having no male help in caring for the offspring. An example is seen in the yellow-rumped honeyguide, a bird whose males defend beehives because the females feed on their wax. As the females approach, the male defending the nest will mate with them. Harem mating structures are a type of polygynous system where certain males dominate mating while controlling a territory with resources. Elephant seals, where the alpha male dominates the mating within the group are an example. A third type of polygyny is a lek system. Here there is a communal courting area where several males perform elaborate displays for females, and the females choose their mate from this group. This behavior is observed in several bird species including the sage grouse and the prairie chicken.

In **polyandrous** mating systems, one female mates with many males. These types of systems are much rarer than monogamous and polygynous mating systems. In pipefishes and seahorses, males receive the eggs from the female, fertilize them, protect them within a pouch, and give birth to the offspring (Figure 36.39). Therefore, the female is able to provide eggs to several males without the burden of carrying the fertilized eggs.

**Figure 36.39** Polyandrous mating, in which one female mates with many males, occurs in the (a) seahorse and the (b) pipefish. (credit a: modification of work by Brian Gratwicke; credit b: modification of work by Stephen Childs)

## Simple Learned Behaviors

The majority of the behaviors previously discussed were innate or at least have an innate component (variations on the innate behaviors may be learned). They are inherited and the behaviors do not change in response to signals from the environment. Conversely, learned behaviors, even though they may have instinctive components, allow an organism to adapt to changes in the environment and are modified by previous experiences. Simple learned behaviors include habituation and imprinting—both are important to the maturation process of young animals.

### Habituation

**Habituation** is a simple form of learning in which an animal stops responding to a stimulus after a period of repeated exposure. This is a form of non-associative learning, as the stimulus is not associated with any punishment or reward. Prairie dogs typically sound an alarm call when threatened by a predator, but they become habituated to the sound of human footsteps when no harm is associated with this sound, therefore, they no longer respond to them with an alarm call. In this example, habituation is specific to the sound of human footsteps, as the animals still respond to the sounds of potential predators.

### Imprinting

**Imprinting** is a type of learning that occurs at a particular age or a life stage that is rapid and independent of the species involved. Hatchling ducks recognize the first adult they see, their mother, and make a bond with her. A familiar sight is ducklings walking or swimming after their mothers (Figure 36.40). This is another type of non-associative learning, but is very important in the maturation process of these animals as it encourages them to stay near their mother so they will be protected, greatly increasing their chances of survival. However, if newborn ducks see a human before they see their mother, they will imprint on the human and follow it in just the same manner as they would follow their real mother.

**Figure 36.40** The attachment of ducklings to their mother is an example of imprinting. (credit: modification of work by Mark Harkin)

The International Crane Foundation has helped raise the world's population of whooping cranes from 21 individuals to about 600. Imprinting hatchlings has been a key to success: biologists wear full crane costumes so the birds never "see" humans. Watch this [video](http://openstaxcollege.org/l/whooping_crane) ([http://openstaxcollege.org/l/whooping\\_crane](http://openstaxcollege.org/l/whooping_crane)) to learn more.

Workers wear a special costume when interacting with whooping crane chicks. Justify the need for this process.

- a. Whooping crane chicks undergo habituation in which the chicks make a bond with the objects they see in the environment. Therefore, workers must wear a special costume to fool the chick into thinking it is associating with an adult whooping crane.
- b. Whooping crane chicks undergo imprinting with the first object they see. Therefore, workers must wear a special costume to fool the chick into thinking it is associating with an adult whooping crane to avoid creating the expectation it will mate with a human.
- c. Whooping crane chicks undergo imprinting with the first few objects they see. Therefore, workers must wear a special costume to fool the chick into thinking it is associating with an adult whooping crane to avoid creating the expectation that it will mate with a human.
- d. Whooping crane undergoes habituation in which the chicks only make a bond with the first object they see. The young chicks only trust that first object to feed them. Thus workers must wear a special costume to fool the chick into thinking it is associating with an adult whooping crane.

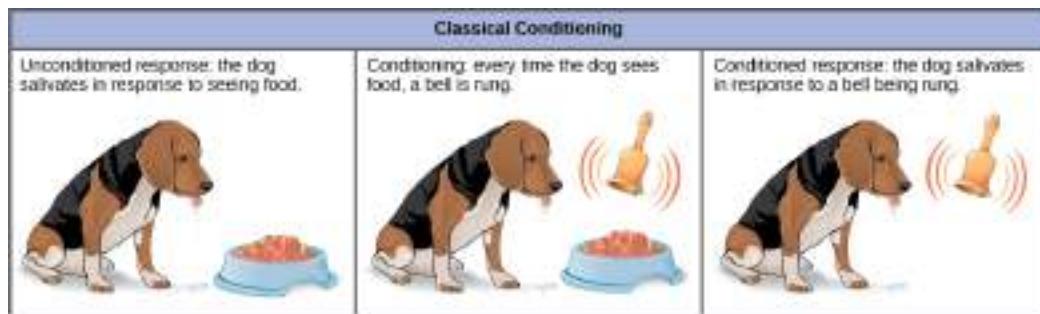

## Conditioned Behavior

**Conditioned behaviors** are types of associative learning, where a stimulus becomes associated with a consequence. During operant conditioning, the behavioral response is modified by its consequences, with regards to its form, strength, or frequency.

### Classical Conditioning

In **classical conditioning**, a response called the conditioned response is associated with a stimulus that it had previously not been associated with, the conditioned stimulus. The response to the original, unconditioned stimulus is called the unconditioned response. The most cited example of classical conditioning is Ivan Pavlov's experiments with dogs ([Figure 36.41](#)). In Pavlov's experiments, the unconditioned response was the salivation of dogs in response to the unconditioned stimulus of seeing or smelling their food. The conditioning stimulus that researchers associated with the unconditioned response was the ringing of a bell. During conditioning, every time the animal was given food, the bell was rung. This was

repeated during several trials. After some time, the dog learned to associate the ringing of the bell with food and to respond by salivating. After the conditioning period was finished, the dog would respond by salivating when the bell was rung, even when the unconditioned stimulus, the food, was absent. Thus, the ringing of the bell became the conditioned stimulus and the salivation became the conditioned response. Although it is thought by some scientists that the unconditioned and conditioned responses are identical, even Pavlov discovered that the saliva in the conditioned dogs had characteristic differences when compared to the unconditioned dog.

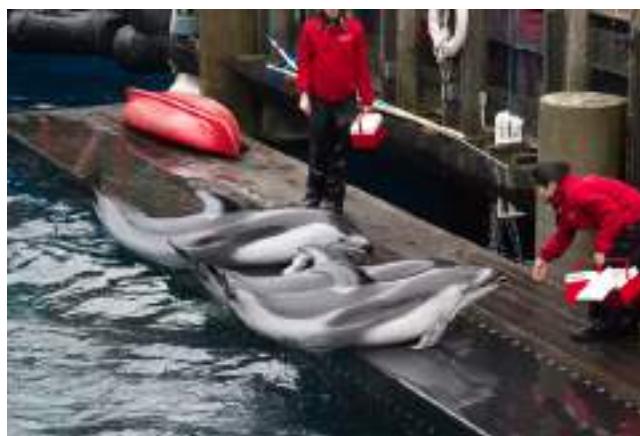

**Figure 36.41** In the classic Pavlovian response, the dog becomes conditioned to associate the ringing of the bell with food.

It had been thought by some scientists that this type of conditioning required multiple exposures to the paired stimulus and response, but it is now known that this is not necessary in all cases, and that some conditioning can be learned in a single pairing experiment. Classical conditioning is a major tenet of behaviorism, a branch of psychological philosophy that proposes that all actions, thoughts, and emotions of living things are behaviors that can be treated by behavior modification and changes in the environment.

### Operant Conditioning

In **operant conditioning**, the conditioned behavior is gradually modified by its consequences as the animal responds to the stimulus. A major proponent of such conditioning was psychologist B.F. Skinner, the inventor of the Skinner box. Skinner put rats in his boxes that contained a lever that would dispense food to the rat when depressed. While initially the rat would push the lever a few times by accident, it eventually associated pushing the lever with getting the food. This type of learning is an example of operant conditioning. Operant learning is the basis of most animal training. The conditioned behavior is continually modified by positive or negative reinforcement, often a reward such as food or some type of punishment, respectively. In this way, the animal is conditioned to associate a type of behavior with the punishment or reward, and, over time, can be induced to perform behaviors that they would not have done in the wild, such as the “tricks” dolphins perform at marine amusement park shows (**Figure 36.42**).

**Figure 36.42** The training of dolphins by rewarding them with food is an example of positive reinforcement operant conditioning. (credit: Roland Tanglao)

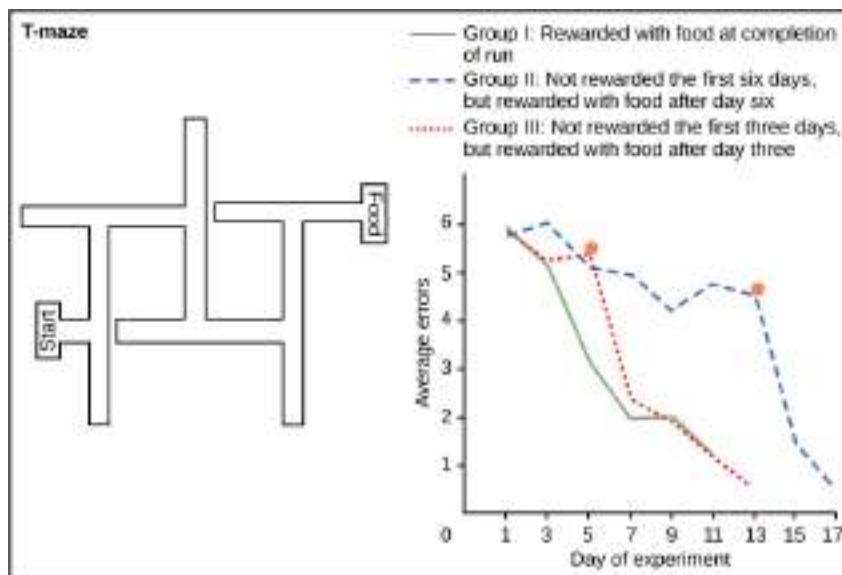

### Cognitive Learning

Classical and operant conditioning are inefficient ways for humans and other intelligent animals to learn. Some primates, including humans, are able to learn by imitating the behavior of others and by taking instructions. The development of complex language by humans has made **cognitive learning**, the manipulation of information using the mind, the most prominent method of human learning. In fact, that is how students are learning right now by reading this book. As students

read, they can make mental images of objects or organisms and imagine changes to them, or behaviors by them, and anticipate the consequences. In addition to visual processing, cognitive learning is also enhanced by remembering past experiences, touching physical objects, hearing sounds, tasting food, and a variety of other sensory-based inputs. Cognitive learning is so powerful that it can be used to understand conditioning in detail. In the reverse scenario, conditioning cannot help someone learn about cognition.

Classic work on cognitive learning was done by Wolfgang Köhler with chimpanzees. He demonstrated that these animals were capable of abstract thought by showing that they could learn how to solve a puzzle. When a banana was hung in their cage too high for them to reach, and several boxes were placed randomly on the floor, some of the chimps were able to stack the boxes one on top of the other, climb on top of them, and get the banana. This implies that they could visualize the result of stacking the boxes even before they had performed the action. This type of learning is much more powerful and versatile than conditioning.

Cognitive learning is not limited to primates, although they are the most efficient in using it. Maze running experiments done with rats by H.C. Blodgett in the 1920s were the first to show cognitive skills in a simple mammal. The motivation for the animals to work their way through the maze was a piece of food at its end. In these studies, the animals in Group I were run in one trial per day and had food available to them each day on completion of the run (**Figure 36.43**). Group II rats were not fed in the maze for the first six days and then subsequent runs were done with food for several days after. Group III rats had food available on the third day and every day thereafter. The results were that the control rats, Group I, learned quickly, and figured out how to run the maze in seven days. Group III did not learn much during the three days without food, but rapidly caught up to the control group when given the food reward. Group II learned very slowly for the six days with no reward to motivate them, and they did not begin to catch up to the control group until the day food was given, and then it took two days longer to learn the maze.

Redrawn after H. C. Blodgett, The effect of the introduction of reward upon the maze performance of rats. Univ. Calif. Publ. Psychol., 1929, 4, No. 8, pages 117 and 120.

**Figure 36.43** Group I (the green solid line) found food at the end of each trial, group II (the blue dashed line) did not find food for the first 6 days, and group III (the red dotted line) did not find food during runs on the first three days. Notice that rats given food earlier learned faster and eventually caught up to the control group. The orange dots on the group II and III lines show the days when food rewards were added to the mazes.

It may not be immediately obvious that this type of learning is different than conditioning. Although one might be tempted to believe that the rats simply learned how to find their way through a conditioned series of right and left turns, E.C. Tolman proved a decade later that the rats were making a representation of the maze in their minds, which he called a “cognitive map.” This was an early demonstration of the power of cognitive learning and how these abilities were not just limited to humans.

## Sociobiology

Sociobiology is an interdisciplinary science originally popularized by social insect researcher E.O. Wilson in the 1970s.<sup>9</sup> Wilson defined the science as “the extension of population biology and evolutionary theory to social organization.” The

9. Edward O. Wilson. *On Human Nature* (1978; repr., Cambridge: Harvard University Press, 2004), xx.

main thrust of sociobiology is that animal and human behavior, including aggressiveness and other social interactions, can be explained almost solely in terms of genetics and natural selection. This science is controversial; noted scientists such as the late Stephen Jay Gould criticized the approach for ignoring the environmental effects on behavior. This is another example of the “nature versus nurture” debate of the role of genetics versus the role of environment in determining an organism’s characteristics.

Sociobiology also links genes with behaviors and has been associated with “biological determinism,” the belief that all behaviors are hardwired into our genes. No one disputes that certain behaviors can be inherited and that natural selection plays a role retaining them. It is the application of such principles to human behavior that sparks this controversy, which remains active today.

### Lab Investigation

*AP<sup>®</sup> Biology Investigative Labs: Inquiry-Based Approach, Investigation 12: Fruit Fly Behavior.* This inquiry-based investigation provides an opportunity for you to design and implement a series of experiments using choice chambers to investigate behaviors that underlie directed movement (taxis) towards or away from environmental stimuli, including chemical signals, light, and temperature, in a small population of *Drosophila*.

### Activity

#### Animal Behavior Field Study

Animal behavior can be studied in nearly every environment. Visit a local park, zoo, athletic field, or even a location on your school campus and observe the behaviors and interactions among different animals and with their environment. Consider the following questions in your study: How do animals exchange information and alter behavior in response to stimuli? What mechanisms do animals use to communicate information? What examples of innate and learned behaviors did you observe? What predictions can you make about observed behavior(s) if environmental conditions change?

#### Think About It

Describe how Pavlov’s dog experiments are an example of classical conditioning. How does operant conditioning that you use to train a pet to do a trick differ from classical conditioning? What type of conditioning describes how you learned that studying likely will improve your grade on an AP<sup>®</sup> test?

## Section Summary

Behaviors are responses to stimuli. They can either be instinctual/innate behaviors, which are not influenced by the environment, or learned behaviors, which are influenced by environmental changes. Instinctual behaviors include mating systems and methods of communication. Learned behaviors include imprinting and habituation, conditioning, and, most powerfully, cognitive learning. Although the connection between behavior, genetics, and evolution is well established, the explanation of human behavior as entirely genetic is controversial.

## KEY TERMS

**age structure** proportion of population members at specific age ranges

**aggressive display** visual display by a species member to discourage other members of the same species or different species

**aposematic coloration** warning coloration used as a defensive mechanism against predation

**Batesian mimicry** type of mimicry where a non-harmful species takes on the warning colorations of a harmful one

**behavior** change in an organism's activities in response to a stimulus

**behavioral biology** study of the biology and evolution of behavior

**biotic potential ( $r_{max}$ )** maximal potential growth rate of a species

**birth rate ( $B$ )** number of births within a population at a specific point in time

**camouflage** avoid detection by blending in with the background.

**carrying capacity ( $K$ )** number of individuals of a species that can be supported by the limited resources of a habitat

**classical conditioning** association of a specific stimulus and response through conditioning

**climax community** final stage of succession, where a stable community is formed by a characteristic assortment of plant and animal species

**cognitive learning** knowledge and skills acquired by the manipulation of information in the mind

**commensalism** relationship between species wherein one species benefits from the close, prolonged interaction, while the other species neither benefits nor is harmed

**competitive exclusion principle** no two species within a habitat can coexist when they compete for the same resources at the same place and time

**conditioned behavior** behavior that becomes associated with a specific stimulus through conditioning

**courtship display** visual display used to attract a mate

**death rate ( $D$ )** number of deaths within a population at a specific point in time

**demographic-based population model** modern model of population dynamics incorporating many features of the  $r$ - and  $K$ -selection theory

**demography** statistical study of changes in populations over time

**density-dependent regulation** regulation of population that is influenced by population density, such as crowding effects; usually involves biotic factors

**density-independent regulation** regulation of populations by factors that operate independent of population density, such as forest fires and volcanic eruptions; usually involves abiotic factors

**distraction display** visual display used to distract predators away from a nesting site

**Emsleyan/Mertensian mimicry** type of mimicry where a harmful species resembles a less harmful one

**energy budget** allocation of energy resources for body maintenance, reproduction, and parental care

**environmental disturbance** change in the environment caused by natural disasters or human activities

**ethology** biological study of animal behavior

**exponential growth** accelerating growth pattern seen in species under conditions where resources are not limiting

**fecundity** potential reproductive capacity of an individual

**fixed action pattern** series of instinctual behaviors that, once initiated, always goes to completion regardless of changes in the environment

**foraging** behaviors species use to find food

**foundation species** species which often forms the major structural portion of the habitat

**habituation** ability of a species to ignore repeated stimuli that have no consequence

**host** organism a parasite lives on

**imprinting** identification of parents by newborns as the first organism they see after birth

**innate behavior** instinctual behavior that is not altered by changes in the environment

**intersexual selection** selection of a desirable mate of the opposite sex

**interspecific competition** competition between species for resources in a shared habitat or environment

**intrasexual selection** competition between members of the same sex for a mate

**intraspecific competition** competition between members of the same species

**island biogeography** study of life on island chains and how their geography interacts with the diversity of species found there

**iteroparity** life history strategy characterized by multiple reproductive events during the lifetime of a species

**J-shaped growth curve** shape of an exponential growth curve

**K-selected species** species suited to stable environments that produce a few, relatively large offspring and provide parental care

**keystone species** species whose presence is key to maintaining biodiversity in an ecosystem and to upholding an ecological community's structure

**kin selection** sacrificing one's own life so that one's genes will be passed on to future generations by relatives

**kinesis** undirected movement of an organism in response to a stimulus

**learned behavior** behavior that responds to changes in the environment

**life history** inherited pattern of resource allocation under the influence of natural selection and other evolutionary forces

**life table** table showing the life expectancy of a population member based on its age

**logistic growth** leveling off of exponential growth due to limiting resources

**mark and recapture** technique used to determine population size in mobile organisms

**migration** long-range seasonal movement of animal species

**monogamy** mating system whereby one male and one female remain coupled for at least one mating season

**mortality rate** proportion of population surviving to the beginning of an age interval that die during the age interval

**mutualism** symbiotic relationship between two species where both species benefit

**Müllerian mimicry** type of mimicry where species share warning coloration and all are harmful to predators

**one-child policy** China's policy to limit population growth by limiting urban couples to have only one child or face the penalty of a fine

**operant conditioning** learned behaviors in response to positive and/or negative reinforcement

**parasite** organism that uses resources from another species, the host

**pioneer species** first species to appear in primary and secondary succession

**polyandry** mating system where one female mates with many males

**polygyny** mating system where one male mates with many females

**population density** number of population members divided by the area or volume being measured

**population growth rate** number of organisms added in each reproductive generation

**population size ( $N$ )** number of population members in a habitat at the same time

**primary succession** succession on land that previously has had no life

**quadrat** square made of various materials used to determine population size and density in slow moving or stationary organisms

**r-selected species** species suited to changing environments that produce many offspring and provide little or no parental care

**reflex action** action in response to direct physical stimulation of a nerve

**relative species abundance** absolute population size of a particular species relative to the population sizes of other species within the community

**S-shaped growth curve** shape of a logistic growth curve

**secondary succession** succession in response to environmental disturbances that move a community away from its equilibrium

**semelparity** life history strategy characterized by a single reproductive event followed by death

**signal** method of communication between animals including those obtained by the senses of smell, hearing, sight, or touch

**species dispersion pattern** (also, species distribution pattern) spatial location of individuals of a given species within a habitat at a particular point in time

**species richness** number of different species in a community

**survivorship curve** graph of the number of surviving population members versus the relative age of the member

**symbiosis** close interaction between individuals of different species over an extended period of time that impacts the abundance and distribution of the associating populations

**taxis** directed movement in response to a stimulus

**zero population growth** steady population size where birth rates and death rates are equal

## CHAPTER SUMMARY

### 36.1 Population Demography

Populations are individuals of a species that live in a particular habitat. Ecologists measure characteristics of populations: size, density, dispersion pattern, age structure, and sex ratio. Life tables are useful to calculate life expectancies of individual population members. Survivorship curves show the number of individuals surviving at each age interval plotted versus time.

## 36.2 Life Histories and Natural Selection

All species have evolved a pattern of living, called a life history strategy, in which they partition energy for growth, maintenance, and reproduction. These patterns evolve through natural selection; they allow species to adapt to their environment to obtain the resources they need to successfully reproduce. There is an inverse relationship between fecundity and parental care. A species may reproduce early in life to ensure surviving to a reproductive age or reproduce later in life to become larger and healthier and better able to give parental care. A species may reproduce once (semelparity) or many times (iteroparity) in its life.

## 36.3 Environmental Limits to Population Growth

Populations with unlimited resources grow exponentially, with an accelerating growth rate. When resources become limiting, populations follow a logistic growth curve. The population of a species will level off at the carrying capacity of its environment.

## 36.4 Population Dynamics and Regulation

Populations are regulated by a variety of density-dependent and density-independent factors. Species are divided into two categories based on a variety of features of their life history patterns: *r*-selected species, which have large numbers of offspring, and *K*-selected species, which have few offspring. The *r*- and *K*-selection theory has fallen out of use; however, many of its key features are still used in newer, demographically-based models of population dynamics.

## 36.5 Human Population Growth

The world's human population is growing at an exponential rate. Humans have increased the world's carrying capacity through migration, agriculture, medical advances, and communication. The age structure of a population allows us to predict population growth. Unchecked human population growth could have dire long-term effects on our environment.

## 36.6 Community Ecology

Communities include all the different species living in a given area. The variety of these species is called species richness. Many organisms have developed defenses against predation and herbivory, including mechanical defenses, warning coloration, and mimicry, as a result of evolution and the interaction with other members of the community. Two species cannot exist in the same habitat competing directly for the same resources. Species may form symbiotic relationships such as commensalism or mutualism. Community structure is described by its foundation and keystone species. Communities respond to environmental disturbances by succession (the predictable appearance of different types of plant species) until a stable community structure is established.

## 36.7 Behavioral Biology: Proximate and Ultimate Causes of Behavior

Behaviors are responses to stimuli. They can either be instinctual/innate behaviors, which are not influenced by the environment, or learned behaviors, which are influenced by environmental changes. Instinctual behaviors include mating systems and methods of communication. Learned behaviors include imprinting and habituation, conditioning, and, most powerfully, cognitive learning. Although the connection between behavior, genetics, and evolution is well established, the explanation of human behavior as entirely genetic is controversial.

## REVIEW QUESTIONS

1. An ecologist is planning to measure both the size and density of a population. Identify the experimental method that can best provide these data.

- a. mark and recapture
- b. mark and release
- c. quadrat
- d. life table

2. Which of the following statements can be made about the mark and recapture method of counting population numbers?

- a. Using quadrats for counting individuals in a population increases the accuracy of the mark and recapture method.
- b. The greater the number of individuals captured during the first round of mark and recapture, the greater is the overall population size.
- c. The mark and recapture method is useful for mammals and birds, but of little use for other organisms.
- d. An underestimate of population size would tend to be observed in cases of studies involving animals that learn to seek out bait.
3. Which type of dispersal pattern is characterized by even spacing between individuals in the population?
- random
  - uniform
  - sparse
  - clumped
4. Identify the best method to show the life expectancy of an individual within a population.
- mark and recapture
  - mark and release
  - quadrat
  - life table
5. Describe how a researcher would best collect data in order to calculate mortality rates within a population.
- For various age groups, count the number of individuals that died and the number that survived within a defined time period.
  - For various age groups, count the number of individuals that were born and the number that died within a defined time period.
  - For each sex, count the number of individuals that were born and the number that survived within a defined time period.
  - For each sex, count the number of individuals that died and the number that were born within a defined time period.
6. What survivorship pattern can be used to describe humans?
- by a type I survivorship curve
  - by a type II survivorship curve
  - by a type III survivorship curve
  - by a type IV survivorship curve
7. Different species have different survival curves. A Type III survival curve would most likely be observed for \_\_\_\_\_.
- a. whales
- b. seals
- c. salmon
- d. polar bears
8. Which of the following is associated with long-term parental care?
- few offspring
  - many offspring
  - semelparity
  - fecundity
9. Which of the following conditions is inversely related with fecundity?
- number of offspring
  - energy budget of parent
  - amount of parental care
  - age of parent
10. When studying a squash beetle native to the Everglades, scientists collected data to compare the squash beetle to another beetle native to the Great Lakes region. What data would be used to compare the beetles' reproductive potential?
- few offspring
  - many offspring
  - semelparity
  - fecundity
11. Albatrosses are birds that can live to age 60 and older. They usually do not start breeding until they reach age 8 or 9, which is relatively late compared to other bird species. Based on this information, explain conditions that might be a risk to the survival of albatrosses.
- increased chance of individuals dying before reproducing
  - decreased life spans of individuals
  - increased chance of offspring dying
  - decreased chances of mating between individuals
12. Frogs are animals with high fecundity. Based on this information, frogs should also have which of the following characteristics?
- high energy budget
  - extensive energy storage for offspring
  - small numbers of offspring
  - little or no parental care
13. Species with limited resources usually exhibit a(n) \_\_\_\_\_ growth curve.

- a. logistic  
 b. logical  
 c. experimental  
 d. exponential
- 14.** Give an example of exponential population growth.  
 a. salamanders adapting to fungal infections  
 b. polar bears living in a warming habitat  
 c. bacteria growing in enriched medium in a lab  
 d. feral cats being trapped and neutered in a suburb
- 15.** If the major food source of seals declines due to pollution or overfishing, how would the seal population be affected?  
 a. The carrying capacity of seals would decrease, as would the seal population.  
 b. The carrying capacity of seals would decrease, but the seal population would remain the same.  
 c. The number of seal deaths would increase but the number of births would also increase, so the population size would remain the same.  
 d. The carrying capacity of seals would remain the same, but the population of seals would decrease.
- 16.** Define carrying capacity of a population and explain whether it changes or remains fixed for a population.  
 a. Carrying capacity is the amount of land needed to support a population, and it is fixed for each population.  
 b. Carrying capacity is the amount of water and food resources required to support a population and it is fixed for each population.  
 c. Carrying capacity is the maximum size of a population that can survive using the available resources and it can vary up or down.  
 d. Carrying capacity is the time needed for a population to reach its maximum size and it can vary up or down.
- 17.** Suppose a pesticide used by farmers wipes out the insect population that feeds a population of bats. Predict the effects of this change on the bat population.  
 a. The carrying capacity of the population will increase.  
 b. The carrying capacity of the population will decrease.  
 c. The carrying capacity of the population will not change.  
 d. The carrying capacity of the population cannot be predicted.
- 18.** Which explanation best defines density-dependent growth regulation?  
 a. a factor that affects population density but not population size  
 b. a factor that affects population size but not population density  
 c. a factor that affects population size regardless of population density  
 d. a factor that affects population size in ways related to population density
- 19.** A forest fire is an example of \_\_\_\_\_ regulation.  
 a. density-dependent  
 b. density-independent  
 c. r-selected  
 d. K-selected
- 20.** Species that have many offspring at one time are usually \_\_\_\_\_.  
 a. r-selected  
 b. K-selected  
 c. both r- and K-selected  
 d. not selected
- 21.** The following statements compare r-selected and K-selected species. Identify the statement that makes an accurate comparison.  
 a. r-selected and K-selected species both have limitations in the amount of energy they can invest in reproduction, so they both use similar strategies.  
 b. r-selected and K-selected species both have limitations in the amount of energy they can invest in reproduction, but they use completely different strategies.  
 c. r-selected and K-selected species use similar reproductive strategies but r-selected species require less energy to reproduce than K-selected species.  
 d. r-selected and K-selected species use different reproductive strategies because r-selected species require less energy to reproduce than K-selected species.
- 22.** If a population moves to a new environment rich in resources, what type of growth curve will it exhibit?  
 a. logistic  
 b. logical  
 c. experimental  
 d. exponential
- 23.** Humans have altered environmental factors that have allowed the human population to grow exponentially. State an example of such a factor.

- a. interspecific competition
- b. age structure
- c. carrying capacity
- d. reproductive strategies

**24.** Humans have altered their own carrying capacity. Explain how humans have changed their carrying capacity and the consequences of this change.

- a. By limiting their own carrying capacity, humans have enabled their population to grow rapidly.
- b. By decreasing their own carrying capacity, humans have enabled their population to grow slowly.
- c. By stabilizing their own carrying capacity, humans have enabled their population to grow steadily.
- d. By increasing their own carrying capacity, humans have enabled their population to grow exponentially.

**25.** Humans have influenced their own carrying capacity in several ways. Some human activities increase carrying capacity while others decrease it. Identify a human activity that has decreased the human carrying capacity of the environment.

- a. agriculture
- b. using large amounts of natural resources
- c. domestication of animals
- d. use of language

**26.** Humans began developing oil as an energy source in the early part of the twentieth century. Explain the relationship between this development and the human carrying capacity of Earth.

- a. Drilling for oil enabled humans to increase food production through the use of machinery, which increased the human carrying capacity of the Earth.
- b. Oil production allowed new transportation methods faster than methods using animals, which decreased the human carrying capacity of the Earth.
- c. Accessing oil as an energy source created increased greenhouse gas emissions, which increased the human carrying capacity of the Earth.
- d. Oil as an energy source enabled humans to enjoy more recreational activities, which decreased the human carrying capacity of the Earth.

**27.** The greatest proportion of young individuals can be found in \_\_\_\_.

- a. economically developed countries
- b. economically underdeveloped countries
- c. countries with zero population growth
- d. countries in Europe

**28.** Explain the correlation between age structure and the level of economic development observed in many countries.

- a. There is no correlation between the characteristics of age structures and the level of economic development.
- b. Countries that are more economically developed tend to have fewer middle-aged individuals and more young individuals than undeveloped countries.
- c. A larger ratio of very young individuals to very old individuals characterizes the age structures of countries with the highest economic development.
- d. Age structures of economically undeveloped countries show greater proportions of children and fewer proportions of elderly people.

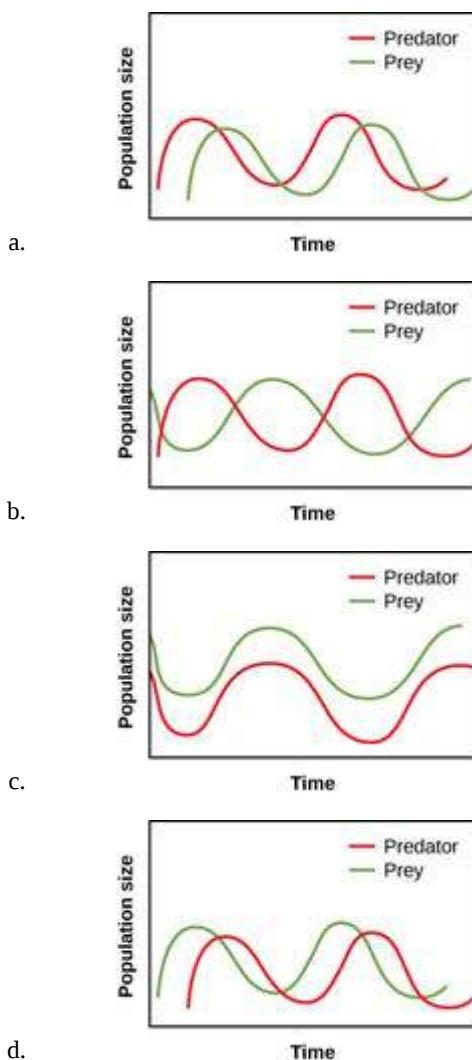

**29.** Which environmental characteristic is likely to increase if the human population continues growing unchecked?

- a. wilderness areas
- b. fresh water supplies
- c. fossil fuel reserves
- d. atmospheric carbon dioxide

**30.** Predict and explain the effects of human population on biodiversity many years in the future.

- a. Biodiversity will decline as human population increases because of habitat loss, increased pollution, and climate change.
- b. Biodiversity will decline as human population increases because of enhanced food supplies, medical advances, and development of renewable energy sources.
- c. Biodiversity will increase as human population increases because of habitat loss, increased pollution, and climate change.
- d. Biodiversity will increase as human population increases because of enhanced food supplies, medical advances, and development of renewable energy sources.

**31.** Analyze the predator-prey graphs to identify the graph that correctly depicts a predator-prey cycle.

**32.** Construct a statement to describe a predator-prey cycle.

- Prey increase in numbers, causing an increase in the predator population, which, in turn, causes a downturn in prey numbers, and leads to a downturn in predator numbers, and then the cycle repeats.
- The number of prey is directly related to the number of predators so that the two populations remain at the same ratio even though the total population numbers fluctuate.
- Increasing prey numbers trigger decreases in predator numbers, which eventually causes a decrease in prey numbers as predators become too sparse, and then the cycle repeats.
- A prey population undergoes a cyclic increasing and decreasing fluctuation in size as its predator population undergoes the same cycle but in a mirror image relationship.

**33.** In a region in Texas, biologists observed that two highly venomous snakes with similar markings deter owl

predators. Upon closer inspection, the snakes were determined to belong to different genera and species. How would these biologists describe the mimicry in this case?

- Batesian mimicry, because it involves nontoxic species that resembles a toxic species.
- Emsleyan/Mertensian mimicry because an extremely toxic species resembles a less toxic species.
- Batesian mimicry because it involves an extremely toxic species that resembles a less toxic species.
- Mullerian mimicry because it involves different species that both produce toxins and display similar warning coloration.

**34.** Explain what would happen to an animal species classified as a Batesian mimic if it did not have its mimicry attributes.

- The animal species would suffer increased loss through predation because its predators would not learn to avoid eating it.
- The animal species would suffer decreased loss through predation because it still produces harmful toxins that would kill its predators.
- The animal species would suffer no long-term loss through predation because it still produces foul tasting compounds that its predators would learn to avoid.
- The animal species would suffer increased loss through predation because predators would not be deterred by its appearance and would find it to be tasty.

**35.** Explain how two different species can coexist in the same habitat according to the competitive exclusion principle.

- Two species can coexist in the same habitat as long as they do not share the same trophic level.
- Two species can coexist in the same habitat as long as they do not share the same mates.
- Two species can coexist in the same habitat as long as they do not share the same resources.
- Two species can coexist in the same habitat as long as they do not share the same life span.

**36.** Explain what would happen if the competitive exclusion principle were violated.

- a. One species will prey on another species and drive it to extinction.
  - b. One species will adapt to another species invading its habitat.
  - c. One species will block another species' access to a critical resource.
  - d. One species will contend with another species for the same resources.
- 37.** Describe the symbiotic relationship of mutualism.
- a. Only one species benefits and the other derives no benefit or harm from the relationship.
  - b. One species benefits and the other is harmed by the relationship.
  - c. Both species benefit from the relationship.
  - d. Neither species benefits nor is either species harmed.
- 38.** Construct a sentence that describes the symbiotic relationships of mutualism, commensalism, and parasitism.
- a. Symbiotic relationships always benefit both species involved.
  - b. Symbiotic relationships never harm either of the species involved.
  - c. Symbiotic relationships always benefit at least one of the species involved.
  - d. Symbiotic relationships always harm at least one of the species involved.
- 39.** Identify the statement that best describes a pioneer species.
- a. A pioneer species is a species that is transported out of its native habitat into a non-native habitat, where there are few or no natural predators to keep the population in check.
  - b. A pioneer species is a species that maintains the community structure in an ecosystem, and whose loss causes the ecosystem to fail.
  - c. A pioneer species is a species that has the greatest influence over the ecosystem usually by bringing most of the energy into the system.
  - d. A pioneer species is a species that can colonize landscapes that are devoid of soil and begin the process of succession.
- 40.** Explain what happens to a forest community after a forest fire.
- a. The same community is quickly re-established just as it existed before the disturbance.
  - b. Another mature community with different species grows quickly in place of the original community.
  - c. Groups of species grow and then are replaced by other groups through a sequential series of changes as the community matures over time.
  - d. The landscape remains barren for many years until trees grow large enough to provide the shade needed for smaller plants to grow.
- 41.** What is innate behavior?
- a. Innate behavior results from practice and conditioning.
  - b. Innate behavior occurs spontaneously without any learning component.
  - c. Innate behavior results from thought processes.
  - d. Innate behavior results from interactions within a social group.
- 42.** What is the difference between innate and learned behaviors?
- a. Innate behaviors can change based on previous experiences, whereas learned behaviors remain the same throughout an organism's life.
  - b. Innate behaviors are controlled by genes, whereas genes play no role in learned behaviors.
  - c. Innate behaviors allow an organism to adapt to new situations by applying previous experiences, whereas learned behaviors allow an organism to respond quickly.
  - d. Innate behaviors are involuntary responses to stimuli, whereas learned behaviors change based on an organism's experiences.
- 43.** Describe phototaxis.
- a. Phototaxis is the directed movement of an organism in response to gravity.
  - b. Phototaxis is the long-range movement of an organism in response to a change in season.
  - c. Phototaxis is the movement of an organism in search of food.
  - d. Phototaxis is the directed movement of an organism in response to light.
- 44.** Monarch butterflies in the eastern regions of North America migrate thousands of miles to an area in Mexico in the fall and then back to northern regions in the spring. Explain how this migration behavior came to be established in this species.

- a. Each new generation learned the migration behavior by observing older generations and mimicking their behavior patterns.
- b. In very early generations of this species, a few individuals found that migration improved their chances for survival and taught their young to carry on the behavior.
- c. Individuals that migrated survived through the winter, whereas individuals that did not migrate died, leading to selection for migration in later generations.
- d. When this butterfly emerged as a new species, by chance it inherited the genetic material that underlies long-distance migration behavior from its ancestor.

**45.** Pheromones are used in communication between some organisms. What is a pheromone?

- a. A pheromone is a type of chemical compound.
- b. A pheromone is a type of display.
- c. A pheromone is a type of language.
- d. A pheromone is a type of song.

**46.** Construct a statement to describe the type of signal used by birds to communicate the presence of a predator to other birds.

- a. Birds release chemical compounds into the air that other birds rapidly recognize as signals of the presence of a predator.
- b. Birds flash visual signals such as wing flapping to communicate warnings to other birds whenever a predator is present.
- c. Birds physically touch other birds using tactile signals when they observe a predator entering their location.
- d. Birds make aural signals such as calls that other birds can hear and learn about a predator that has been observed in the area.

**47.** The sacrifice of the life of an individual so that the genes of relatives may be passed on is called \_\_\_\_.

- a. operant conditioning
- b. kin selection
- c. kinesis
- d. imprinting

**48.** Cite an example that describes how an animal expends energy in finding, selecting, or winning a mate.

- a. Female swallows engage in aggressive harassment of a hawk during breeding season.
- b. Male cardinals harass and peck at other male cardinals in their territory.
- c. Both male and female squirrels build nests out of leaves, twigs, and other plant material.
- d. Female black widow spiders eat males following copulation.

**49.** The term polyandry comes from the Greek words for ‘many’ and ‘man.’ Based on these word origins, describe a polyandrous mating system.

- a. One male mates with many females.
- b. One female mates with one male.
- c. One female mates with many males.
- d. Many females mate with one male.

**50.** Describe an advantage of a monogamous relationship.

- a. Having a lot of males around to provide assistance with protecting and feeding offspring ensures that offspring have the best chance of surviving.
- b. When very few males are available in a population, this mating system makes sure that each male has a mating partner.
- c. In populations where very few females are available, this mating system ensures that no eggs are wasted.
- d. The constant presence of one male throughout the offspring rearing process makes it more likely that offspring will survive and be healthier.

**51.** The ability of rats to learn how to run a maze is an example of cognitive learning. Describe what happens during cognitive learning.

- a. Cognitive learning is a type of learning that occurs early in an animal’s development when it learns to bond to an object or animal.
- b. Cognitive learning occurs when an animal learns to associate a stimulus with a behavior not normally associated with that stimulus.
- c. Cognitive learning occurs when an animal learns a behavior in response to a positive stimulus or negative stimulus.
- d. Cognitive learning is the most complex type of learning that involves multiple types of brain processes to carry out.

**52.** Contrast classical conditioning and operant conditioning.

- a. In operant conditioning, the animal learns to associate a voluntary behavior with its consequences, whereas in classical conditioning, the animal learns to associate a non-voluntary behavior with an unusual stimulus.
- b. In operant conditioning, the animal does not learn a new behavior in response to a stimulus, whereas in classical conditioning, the animal learns to associate a non-voluntary behavior with an unusual stimulus.
- c. In operant conditioning, the animal learns to associate a voluntary behavior with its consequences, whereas in classical conditioning, the animal does not learn a new behavior in response to a stimulus.
- d. In operant conditioning, the animal learns to associate a non-voluntary behavior with an unusual stimulus, whereas in classical conditioning, the animal learns to associate a voluntary behavior with its consequences.

## CRITICAL THINKING QUESTIONS

53. Describe how a researcher could determine the population size and density of a bird population on one of the Hawaiian islands.

- a. Population size can be determined by life tables. The area of the island in square kilometers is divided by the population size to determine the density of the bird population.
- b. Population size can be determined by the mark and recapture method. The population size is divided by the area of the island in square kilometers to determine the density of the bird population.
- c. Population size can be determined by life tables. The population size is divided by the area of the island in square kilometers to determine the density of the bird population.
- d. Population size can be determined by the mark and recapture method. The area of the island in square kilometers is divided by the population size to determine the density of the bird population.

54. Give examples of how two different populations of organisms might have the same population density, but different dispersal patterns.

- a. Two populations could occupy the same range with the same number of individuals, giving different dispersal patterns. However, both the populations may be dispersed randomly throughout the range, giving identical population densities.
- b. Two populations could occupy the different range with the different number of individuals, giving different dispersal patterns. However, both the populations may move over this range in a herd, giving identical population densities.
- c. Two populations could occupy the same range with the different number of individuals, giving identical population densities. However, one population may move over this range in a herd while the other population may be dispersed randomly throughout the range.
- d. Two populations could occupy the same range with the same number of individuals, giving identical population densities. However, one population may move over this range in a herd while the other population may be dispersed randomly throughout the range.

55. A population is observed to have very large numbers of very young individuals, but very low numbers of sexually mature individuals. What hypothesis might a researcher propose about mortality patterns in this population and how would a researcher follow up to test their hypothesis?

- a. A researcher might propose the mortality rate of this species is very high during the developmental period after sexual maturity is reached. This hypothesis can be tested by constructing a life table and calculating mortality rates at different age intervals.
- b. A researcher might propose the mortality rate of this species is very high during the developmental period before sexual maturity is reached. This hypothesis can be tested by using the mark and recapture method and calculating population densities.
- c. A researcher might propose the mortality rate of this species is very high during the developmental period before sexual maturity is reached. This hypothesis can be tested by constructing a life table and calculating mortality rates at different age intervals.
- d. A researcher might propose the mortality rate of this species is very low during the developmental period before sexual maturity is reached. This hypothesis can be tested by constructing a quadrat and calculating mortality rates at different age intervals.
- 56.** An organism, such as an elephant, that invests in long-term care of its offspring faces risks to its survival as a result of this investment. Explain those risks.
- a. Organisms that invest in long-term parental care have many offspring. Having many offspring means there is greater risk of rapid increase in population.
- b. Organisms that invest in long-term parental care have few offspring. Having a limited number of offspring means there is greater risk to the survival of the species when a single offspring dies.
- c. Organisms that invest in long-term parental care have many offspring. Having many offspring means there is greater risk to the survival of the species when a single offspring dies.
- d. Organisms that invest in long-term parental care have few offspring. Having a limited number of offspring means there is greater risk of rapid increase in population.
- 57.** A honey bee colony contains one queen, hundreds of drones, and many thousands of worker bees. The queen produces eggs, the drones produce sperm, and the workers are sterile. Explain how the reproductive strategy of honey bees benefits the survival of the species. (credit: Food and Agriculture Organization of the United Nations)
- a. The fertile queen and drones produce many offspring while sterile worker bees do not benefit the survival of the species.
- b. Worker bees produce many offspring while the sterile queen and drones do not benefit the survival of the species.
- c. The sterile queen and drones use the energy taken in by them for their own growth, growth and maintenance of the hive, and protection and nurturing of offspring.
- d. Sterile worker bees use the energy taken in by them for their own growth, growth and maintenance of the hive, and protection and nurturing of offspring.
- 58.** Two different plant species expend approximately the same amount of energy on reproduction, yet one produces many seeds in a season and the other produces very few. Explain what is likely to be true of the seeds of these two species.
- a. In the plant species that produces many seeds, most of the energy is used to produce seeds, of which only a few will germinate and produce another plant. In the species that produces few seeds, most of the energy is used to increase the chances of seeds produced to germinate and grow into an adult plant.
- b. In a plant species that produces many seeds, most of the energy is used to produce seeds, most of which will germinate and produce another plant. In a species that produces few seeds, most of the energy is used to increase the chances of seeds produced to germinate and grow into an adult plant.
- c. In a plant species that produces many seeds, most of the energy is used to produce seeds, of which only a few will germinate and produce another plant. In a species that produces few seeds, most of the energy is used to reduce the chances of seeds produced to germinate and grow into an adult plant.
- d. In a plant species that produces many seeds, most of the energy is used to increase the chances of seeds produced to germinate and grow into an adult plant. In a species that produces few seeds, most of the energy is used to produce those seeds, which will germinate and produce another plant.

- 59.** Explain how  $r_{max}$  would be expected to differ for an elephant and a flea, and how that changes the time scale over which populations of these two animals would be studied.

- a.  $r_{max}$  would be greater for an elephant as elephant reproduces at a faster rate than flea. A shorter time scale would be used to study changes over several elephant generations.
- b.  $r_{max}$  would be greater for a flea as flea reproduces at a faster rate than elephant. A shorter time scale would be used to study changes over several flea generations than over several elephant generations.
- c.  $r_{max}$  would be greater for a flea as flea reproduces at a faster rate than elephant. A longer time scale would be used to study changes over several flea generations than over several elephant generations.
- d.  $r_{max}$  would be greater for an elephant as the elephants grow at an exponential rate so the population growth rate is greatly increased. A shorter time scale would be used to study changes over several elephant generations.

**60.**

| Date    | N   |
|---------|-----|
| 5/1/12  | 56  |
| 6/1/12  | 98  |
| 7/2/12  | 203 |
| 8/10/12 | 421 |

These data were collected on a population of beetles in Florida. Based on the data, how would you describe population growth in this case and what do you predict about growth of this population in the future? Explain your reasoning.

- a. Population shows logistic growth, as number of individuals doubles every month and will likely continue to grow logically until its resources become depleted. At that point, the population growth rate will slow down and level off to zero.
- b. The population shows exponential growth, as the number of individuals doubles every month and will likely grow logically in the future when the resources become limited. At that point, the population growth rate will slow down and level off to zero.
- c. The population shows exponential growth, as number of individuals doubles every month and will likely continue to grow exponentially until its resources become limited. At that point, the growth will become logistic; the population growth rate will slow down and level off to zero.
- d. The population shows logistic growth and is likely to grow exponentially as the resources are probably increasing. The population growth rate will increase in the future as well.

**61.** Explain how climate change might lead to a decrease in one population's carrying capacity and an increase in the carrying capacity of a different population.

- a. Plant species that are drought-resistant would decline in warm temperatures whereas other species would thrive in number in such a climate.
- b. Plant species that are pest-resistant would thrive in warm temperatures whereas other species would decline in number in such a climate.
- c. Plant species that are drought-resistant would decline in cold temperatures whereas other species would thrive in number in such a climate.
- d. Plant species that are drought-resistant would thrive in warm temperatures whereas other species would decline in number in such a climate.

**62.** Compare and contrast density-dependent growth regulation with density-independent growth regulation. Give an example of each as they might affect a caterpillar population.

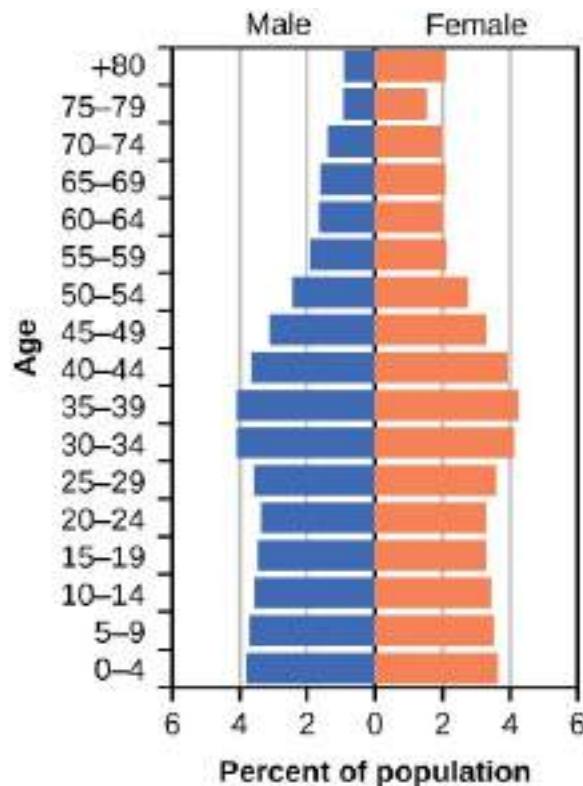

- a. Both are environmental conditions that result in changes in population numbers. Density-independent factors have different effects on population densities whereas density-dependent factors have the same effect. An example of the former is a caterpillar population being kept low by a pesticide because it kills them regardless of their numbers. In the case of the latter, a large caterpillar population leads to a decrease in food availability, which will cause the caterpillar population to decline.
- b. Both are environmental conditions that result in changes in population numbers. Density-independent factors have the same effect at all population densities whereas density-dependent factors have different effects. An example of the former is of a caterpillar population being kept low by a pesticide because it kills them regardless of their numbers. In the case of the latter, a large caterpillar population leads to a decrease in food availability, which will cause the caterpillar population to decline.
- c. Both are environmental conditions that result in changes in population numbers. Density-independent factors have the same effect at all population densities whereas density-dependent factors have different effects. An example of the former is of a caterpillar population being kept low by a pesticide because it kills them when their numbers are low. In the case of the latter, a large caterpillar population leads to a decrease in food availability, which will cause the caterpillar population to decline.
- d. Both are environmental conditions that result in changes in population numbers. Density-independent factors have the same effect at all population densities whereas density-dependent factors have different effects. An example of the former is of a caterpillar population being kept low by a pesticide because it kills them regardless of their numbers. In the case of the latter, a large caterpillar population leads to a decrease in food availability, which will cause the caterpillar population to increase.
- 63.** Why doesn't a frog, which is an r-selected species, care for its offspring in the way a wolf, which is a K-selected species, cares for its offspring?
- a. Frogs have been selected by stable, predictable environments, therefore they do not feel the need to care for their offspring like wolves.
- b. Frogs use very little energy to produce large numbers of offspring, therefore they do not have enough remaining to nurture them.
- c. Smaller animals like frogs do not care for their offspring as a lot of them are produced whereas larger animals like wolves only produce a few.
- d. Frogs expend a lot of energy to produce large numbers of offspring, therefore they do not have enough to nurture them.
- 64.** Explain which features of a logistic growth curve are the same for every population exhibiting logistic growth and which features might vary from one population to another.
- a. The overall S-shape would be the same for all populations. The actual x-y values on the graphs, population numbers corresponding to starting populations, and the ending carrying capacities could differ.
- b. The overall carrying capacities would be the same for all populations. The actual x-y values on the graph and population numbers corresponding to the starting populations could differ.
- c. The overall S-shape would be the same for all populations showing logistic growth. The only factor that could differ is the actual x-y values on the graphs indicating the time frames for the growth curves.
- d. The x-y values on the graphs indicating the time frames for the growth curves would be the same. Overall S shape and population numbers corresponding to the starting populations could differ.
- 65.** Explain why the concept of carrying capacity is important when discussing human population growth.

- Humans can decrease the carrying capacity of their environment by developing food production methods and engineering high quality shelters, which enables more people to live than would otherwise be possible.
- Humans have been able to change the carrying capacity of their environment, which enables more people survive. By decreasing their own carrying capacity, humans are responsible for their population boom.
- Humans have been able to change the carrying capacity of their environment, which enables more people to live. By increasing their own carrying capacity, humans are responsible for their population boom.
- Humans can increase the carrying capacity of their environment by developing food production methods and engineering high quality shelters, which enables fewer people to live than would otherwise be possible. This would result in population collapse.

**66.** The Industrial Revolution began with the invention of the steam engine. At about the same time, human population began increasing exponentially. Explain how these two events are linked to the idea that humans are able to change the carrying capacity of their environment.

- The invention of the steam engine enabled people to use machines to carry out farming activities. The amount of available resources needed to sustain human life increased with the invention of machines. This increase in resources spurred exponential population growth.
- The invention of the steam engine enabled people to develop pest-resistant crop varieties. The amount of available resources needed to sustain human life increased with the invention of machines. This increase in resources spurred exponential population growth.
- The amount of available resources needed to sustain human life decreased with the invention of machines, but the carrying capacity increased. This increase in carrying capacity spurred exponential population growth.
- The invention of the steam engine enables the environment to be changed according to the needs of the people. This regulation of environmental conditions spurred exponential population growth.

This diagram shows the age structure for a country. Analyze the age structure and use it to predict the economic status of this country. Explain your reasoning.

- This country is likely to be an economically developing country because it has a fairly even distribution of individuals in all age groups.
- This country is likely to be an economically developed country because it has many more very young people and very few old people.
- This country is likely to be an economically developed country because it has a fairly even distribution of individuals in all age groups.
- This country is likely to be an economically undeveloped country because it has many more very young people and very few old people.

The global ecological footprint is defined as the total land area needed to supply all of the resources consumed by all humans. This graph shows the relationship between time and the global human footprint measured in number of planet Earths. Analyze the graph, and use it to explain what has been the consequence of human population change so far. Then, predict the consequences of continued population change in the future.

- The water resources present on Earth has been exceeded by the human population. If the human population keeps increasing, the ecological footprint of humans will increase far beyond the ability of Earth to support human population and our population could crash.
- The land area present on Earth to supply our resources has been exceeded by the human population. If the human population keeps increasing, the ecological footprint of humans will increase far beyond the ability of Earth to support human population and our population could crash.
- The land area present on Earth to supply our resources has been exceeded by the human population. If the human population keeps increasing, the birth and death rates will decrease and our population could crash.
- The water resources present on Earth has been exceeded by the human population. If the human population keeps increasing, the birth and death rates will decrease and our population could crash.

69.

This graph shows a predator-prey cycle for wolves and moose. Explain why the graphs do not resemble the idealized graphs used as models of the predator-prey cycle.

- This graph reflects all of the influences on both populations in addition to the predator-prey influences.
- This graph reflects all of the influences on both populations, but not the predator-prey influences.
- This graph reflects just the influence of predator-prey interactions on both populations.
- This graph reflects some of the influences on both populations other than the predator-prey influences.

70. Suppose a population of lizards becomes divided into two groups on two different islands after a devastating tsunami. No predators of the lizard are present on one island, and on the other island is a fierce predator that uses the lizard as its primary source of food. Assuming both populations encounter similar environments in every other way, and both survive and grow over the next 100 years, how do you predict any of the characteristics of the two lizard populations to differ at the end of that time? Give specific examples to explain your prediction.

- a. The lizards on the island with no predators will likely evolve adaptations such as camouflaged coloration, sharp spines, or toxins to defend against this predator. These adaptations will likely be absent in the other population because they are adapted to other predators.
- b. The lizards that survive the fierce predator will likely evolve adaptations such as camouflaged coloration, sharp spines, or toxins to defend against this predator. These adaptations will likely be absent in the other population because they are adapted to other predators.
- c. The lizards that survive the fierce predator will likely evolve adaptations such as camouflaged coloration, sharp spines, or toxins to defend against this predator. These adaptations will likely be absent in the other population because this predator is not a factor in their survival.
- d. The lizards on the island with no predators will likely evolve adaptations such as camouflaged coloration, sharp spines, or toxins to defend against this predator. These adaptations will likely be absent in the other population because they have survived this predator.

**71.** The downy woodpecker and the hairy woodpecker are two species that live in the same habitats. The downy woodpecker is slightly smaller and has a smaller beak than the hairy woodpecker. The downy woodpecker uses its bill to search for food on small twigs and branches while the hairy woodpecker is most often observed searching for food on tree trunks. Explain how the competitive exclusion principle relates to this example.

- a. Both woodpeckers have identical bill structure, but do not access their food from the same places in the habitat. They do not directly compete with one another for food and thus, can coexist in the same habitat.
- b. Both live in the same habitat and have some similarities, but access their food from the same places in the habitat. In this way, the two species can coexist in the same habitat.
- c. Both woodpeckers share similarities in their bill structures. So, they directly compete with one another for food. This directly relates to competitive exclusion principle.
- d. Both live in the same habitat and have some similarities, but do not access their food from the same places in the habitat. In this way, the two species can coexist in the same habitat.

**72.** Honey bees are pollinators. Identify the type of symbiotic relationship that exists between honey bees and flowering plants, and explain why your reasoning.

- a. This is commensalism because bees help plants pollinate and, in turn, obtain nectar from the plants.
- b. This is a mutualistic relationship, because bees obtain nectar from the plants, but do not provide any benefits to the plants.
- c. This is commensalism, because bees obtain nectar from the plants, but do not provide any benefits to the plants.
- d. This is a mutualistic relationship, because bees help plants pollinate and, in turn, obtain nectar from the plants.

**73.** Prairie dogs are considered a keystone species in the western U.S. because of their extensive burrowing activities and their role as a prey animal. Explain why these characteristics would result in the keystone role of prairie dogs in their ecosystem.

- a. Prairie dogs provide protection and shelter for small animals and harm predator animals in the ecosystem.
- b. Without the prairie dogs, the ecosystem might collapse due to lack of protection and shelter for small animals and lack of prey to sustain large predator animals.
- c. Prairie dogs dig underground burrows, reducing aeration in the soil and preventing excessive growth of plants above ground.
- d. The burrows prairie dogs dig underground provide shelter for other species of animals as well as protection from predators, but prevent growth of plants above ground.

**74.**

| Raised by parents of species A | Contact calls made to other members of the flock | Alarm calls made in response to predator sighting |
|--------------------------------|--------------------------------------------------|---------------------------------------------------|
| Species A chicks               | Species A call                                   | Species A call                                    |
| Species B chicks               | Species A call                                   | Species B call                                    |

Mating pairs of two different species of parrots sometimes lay their eggs in the same nest. When this happens, only one mating pair ends up parenting the chicks even though chicks of both species may be present. The chicks in such mixed nesting groups displayed some interesting behaviors summarized in the table. Classify these behaviors as innate or learned, and explain how they compare.

- a. An alarm call is an innate behavior and a contact call is a learned behavior. Innate behavior comes out automatically in response to a stimulus whereas learned behavior develops over time after observing other birds carrying out the behavior.
- b. The alarm call is a learned behavior and contact call is an innate behavior. Learned behavior develops over time after observing birds carrying out the behavior whereas innate behavior comes out automatically in response to a certain stimulus.
- c. The alarm call is an innate behavior and contact call is a learned behavior. Innate behavior develops over time in response to stimulus after continuous exposure. Learned behavior develops over time after observing other birds carrying out their behavior.
- d. The alarm call is a learned behavior and contact call is an innate behavior. Learned behavior comes out automatically whereas innate behavior develops over time in response to stimulus after continuous exposure.

**75.** Mammals such as humans show a behavior known as the flight or fight response. Explain how natural selection was likely involved in the development of this behavior that can be observed in humans today.

- a. Individuals showing fight or flight behavior were more likely to survive than individuals lacking the trait. This trait got randomly selected by natural selection, thus became preferentially incorporated into the human lineage.
- b. Individuals showing fight or flight behavior were more likely to survive than individuals lacking the trait. Sudden, inheritable changes were naturally selected, which included the fight or flight behavior. Thus, this response was incorporated into the human lineage.
- c. Individuals showing fight or flight behavior were more likely to survive than individuals lacking this trait. Therefore surviving individuals passed on their trait to offspring while non-surviving individuals do not. Thus, this response became incorporated into human lineage.
- d. Individuals showing fight or flight behavior were not more fit than individuals lacking this trait. However, the trait was selected by natural selection due to a random chance event in the gene frequency of individuals showing fight or flight behavior.

**76.** A researcher studying minnows, a type of fish, kept two groups of 20 fish in separate containers. The containers were linked by a pair of small tubes outfitted with a pump that constantly circulated water between both tanks. The researcher observed both groups of fish after

placing a larger fish known to be a predator of minnows into one of the tanks. Fish in both tanks demonstrated alarm behavior. How can you explain these observations?

- a. Fish in the tank that received the predator released alarm signals in chemical form. These compounds circulated and reached the other tank, eliciting an alarm response from the fish there nonetheless.
- b. Fish in the tank that received the predator released alarm signals in the form of electrical signals. These compounds circulated and reached the other tank, eliciting an alarm response from the fish there nonetheless.
- c. The predator introduced in one tank of fish released alarm signals in chemical form. These compounds circulated and reached the other tank, eliciting an alarm response from the fish there nonetheless.
- d. Fish in the tank that did not receive the predator released alarm signals in the chemical form. These compounds circulated and reached the other tank and elicited an alarm response from the fish.

**77.** In some species, males expend a lot of energy in courtship rituals, whereas in other species, males expend much less energy in other ways of attracting mates such as producing colorful plumage. What does this mean for any energy that left over males of these species might have to devote to care for offspring?

- a. Males of species carrying out courtship rituals assist in parental care whereas males that use colorful plumage to attract mates do not assist with the parental care.
- b. Males of species carrying out courtship rituals do not assist in parental care whereas males that use colorful plumage to attract mates have energy available to assist with parental care.
- c. Males of species carrying out courtship rituals as well as species of males that use colorful plumage to attract mates, both would assist with the parental care.
- d. Males of species carrying out courtship rituals as well as species of males that use colorful plumage to attract mates would not assist in parental care as the females would be involved.

**78.** Female spotted sandpipers fight each other for resource-rich territories on their beach breeding grounds. Based on this, which mating type would most likely be operating in this species? Explain your reasoning.

- a. Polyandrous mating is most likely operating as the females are establishing territories apart from other females. The females will then attract males to the resources they control which will result in many males attracted to few females with the richest territories.
- b. Polygynous mating is most likely operating as the females are establishing territories apart from other females. The females from all territories would attract males to the resources they control, which would result in few males attracted to many females in each territory.
- c. Polyandrous mating is most likely operating as the females are establishing territories apart from other females. The females from all territories would attract males to the resources they control, which would result in few males attracted to many females in each territory.
- d. Polygynous mating is most likely operating as the females are establishing territories apart from other females. The females will then attract males to the resources they control which would result in many males attracted to few females with the richest territories.

**79.** Describe Pavlov's dog experiments as an example of classical conditioning.

- a. Pavlov demonstrated classical conditioning through a maze running experiment with the dog. The motivation for the dog to work its way through the maze was a piece of food at the end of the maze. The dog ran in one trial per day and had food available at the end of the run.
- b. Pavlov hung a chicken piece in a cage too high for the dog to reach and several boxes were placed randomly on the floor. Eventually the dog was able to stack the boxes and climb on top to get the chicken piece through classical conditioning.
- c. Pavlov put a dog in a large box that contained a lever that would dispense food to the dog when pressed. While initially the dog would push the lever a few times by accident, it eventually associated pushing the lever with getting the food through classical conditioning.
- d. Pavlov sounded a bell whenever food was presented to a dog, which produced saliva in response to the sight or smell of the food. Through classical conditioning, the dog started responding to the bell ringing with salivation as the dog came to associate the bell sound with the arrival of food.

## TEST PREP FOR AP® COURSES

**80.** A researcher has been tracking a population of turtles. The researcher marked 200 young turtles just after hatching. A year later, collection data reveal that about 80% survived. A year after that, collection data revealed that about 60% of the original group was still living. After a third year, about 40% could be found alive. What do these data say about the survivorship curve that would best describe this population? Explain your reasoning.

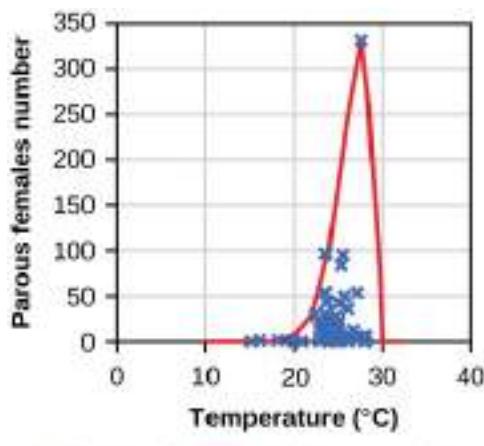

- a. Type II survivorship curve because the number of survivors decreases by the same value (20%) every year.
- b. Type I survivorship curve because the number of survivors decreases by the same value (20%) every year.
- c. Type II survivorship curve because the number of survivors increases by the same value (20%) every year.
- d. Type IV survivorship curve because the number of survivors decreases by the same value (20%) every year.

**81.** After discovering a new species of salamander in a forest ecosystem, a researcher set traps at many different locations within the forest and collects data from his traps. The researcher's goal was to determine which types of environments within the forest the salamander is most likely to be found. Construct another scientific question

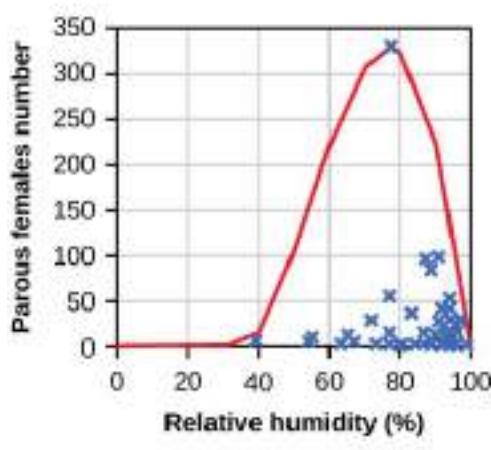

the researcher can answer using the data he has already collected to further refine his study of this species.

- a. What is the population distribution of this salamander species in this ecosystem?
- b. What is the rate of population growth of this salamander species in this ecosystem?
- c. Which animal species prey on this salamander species in this ecosystem?
- d. What abiotic resources are essential for the survival of this salamander species in this ecosystem?

These graphs summarize data collected in an area of Brazil between 2005 and 2006. Researchers captured mosquitoes and counted the number of parous females. Parous females are females that produced viable offspring. Based on the information given, how would mosquito populations change in Brazil if the climate shifted to very hot (above 30°C) and very dry (below 60% humidity) conditions for an extended period of time? Explain your reasoning.

- a. The mosquito populations would decrease at temperatures above 30°C, as this is the upper limit for parous females, leading to a drop in offspring production. Below 60% humidity not much change would be seen in the population of mosquitoes.
- b. The mosquito populations would decrease, possibly reaching zero. As temperatures above 30°C are the upper limit for parous females, offspring production would drop. Drier conditions would do the same.
- c. The mosquito populations would stay the same. This would be because temperature above 30°C and humidity below 60% is close to the favorable conditions of offspring production by parous females.
- d. The mosquito populations would stay the same at temperatures above 30°C as higher temperatures will not affect the production of viable offspring by parous females. Drier conditions, below 60% humidity, would cause a drop in the population, as it is the lower limit for offspring production.

Researchers were interested in answering the question, “How does sheep grazing affect the population densities of wild mountain birds?” To answer this question, the researchers counted population numbers of various birds in areas of low intensity sheep grazing and in areas of high intensity sheep grazing. A third set of data was collected from control areas in which no sheep grazing occurred. The results of this study are shown in these graphs. All of the bird species eat insects as their primary source of nutrition. The group labeled “insect eaters” combines many species because the numbers for individual species were too small to show separately as shown for the meadow pipit and willow grouse, which are both highly abundant. Because all of the birds are insect eaters, construct a scientific question related to this fact that the researchers could ask to refine their study even further. Explain your reasoning.

- a. Does sheep grazing make insects more available to birds? This question refines the question about how sheep grazing affects bird populations because it asks more specifically how sheep grazing changes the food availability for the birds.
- b. How does sheep grazing make insects more available to birds? This question refines the question about how sheep grazing affects insect populations because it asks more specifically how sheep grazing changes the food availability for the insects.
- c. Does sheep grazing make insects more available to birds? This question refines the question about how sheep grazing affects bird populations because it asks more specifically how sheep grazing changes the food availability for the insects.
- d. How does sheep grazing make insects more available to birds? This question refines the question about how sheep grazing affects bird populations because it asks more specifically how sheep grazing changes the food availability for the insects.

**84.** A pond ecosystem in an open field begins to be shaded by the growth of trees around its perimeter. Predict changes in this pond after the trees grow large enough to completely shade the pond.

- a. The population sizes of all organisms will decrease in response to lower energy flowing into the pond.
- b. The population densities of all organisms will increase in response to lower temperatures in the pond.
- c. The population distributions of large organisms will shift from clumped to random in response to lower energy flowing into the pond.
- d. The population distributions of small organisms will shift from uniform to clumped in response to lower temperatures in the pond.

**85.** A researcher has been studying a wildflower population growing in a large meadow. The researcher counted individual plants and mapped their locations. Analysis of the data revealed that the wildflower has a uniform population distribution. This result prompts the researcher to ask a new scientific question to further refine his understanding of the ecology of this plant species. Construct a scientific question the researcher might ask that is directly prompted by his first set of findings.

- When does this plant species flower and how does it attract pollinators?
- Does this wildflower species have any adaptations that function to defend the plant against herbivores?
- Which species of insects and/or birds are pollinators for this wildflower species?
- Does this wildflower species secrete any chemical compounds that inhibit growth of others of its species?

**86.** Fruit flies are found in many different areas in the world. Fruit flies that are resistant to cold temperatures tend to have decreased fecundity at early ages compared to flies that are not capable of surviving the cold. Explain a likely reason for why this set of traits is observed. (credit: Anthony Zera Publications)

- Flies having traits that traded early reproductive energy for greater storage of energy in their bodies were favored via natural selection because they survived the cold better than flies that did not have these traits.
- In cold conditions, flies have less need for reproduction than in warm conditions and so energy normally used for reproduction is diverted to other survival functions.
- Flies respond to weather conditions to shift their energy resources to either storage in their bodies in the cold or to reproduction when conditions become warm again.
- All fruit flies have the same genetic makeup, but express different patterns of genes under different conditions, which results in expression of certain genes for cold conditions and others for warm conditions.

Female parasitoid wasps lay their eggs inside the bodies of caterpillars. The caterpillars die when the eggs hatch, and the young wasps feed on the body of the caterpillar. Egg-laying females of two species of parasitoid wasps were studied in special growth chambers in which a food source was either provided or omitted. This table summarizes some of the data collected. Identify the statement most consistent with these data.

- When energy availability is low, females put more energy than normal into producing offspring.
- When energy availability is high, females produce offspring with higher viability.
- When energy availability is low, females shift energy away from reproduction and toward their own survival.
- When energy availability is high, females cannot both produce viable offspring and maintain their own survival.

**88.** During breeding season, many female elk mate with males, but not all mated females become pregnant. Female elk having body fat less than 6% were found to have

greatly reduced chances of becoming pregnant than female elk having body fat above 10%. Explain how natural selection was likely involved in establishing this trait in elk. (credit: USGS Northern Prairie Wildlife Research Center)

- Through natural selection, female elk that did not have the energy reserves to carry a pregnancy to term and did not become pregnant died whereas those which became pregnant anyway were favored.
- Natural selection favored the selection of traits preventing pregnancies in female elk with low fat reserves, so this trait has become predominant in natural elk herds observed today.
- Natural selection randomly changes the frequency of genes allowing traits preventing pregnancies in female elk with low fat reserves to be favored.
- Natural selection leads to a sudden inheritable change in the genome of the female elk, ensuring female elk with very high fat reserves to effectively carry out pregnancy.

**89.** Research on elk in Yellowstone National Park was conducted to determine how body condition affects survival of the elk over the winter months. It was found that the probability of survival of female elk is greater when they have accumulated 15% or more body fat by the end of fall. Female elk with body fat less than 10% in late fall were found to be at high risk of not surviving the winter. Explain why this pattern is likely to be observed. (credit: USGS Northern Prairie Wildlife Research Center)

- In winter, the availability of food decreases. So, there needs to be a certain threshold level of energy their bodies store in the form of fat to ensure their survival.
- In winter, the availability of food increases. So, there should be a certain threshold level of energy in their bodies stored in the form of fat to ensure their survival.
- In winter, elk's requirement for food increases due to increase in metabolic activities. So, there should be a certain threshold level of energy in their bodies stored in the form of fat to ensure their survival.
- Elk release more energy in winter. So, there should be a certain threshold level of energy in their bodies stored in the form of fat to ensure their survival.

| 13               | 121                   |
| 14               | 122                   |

These data were collected on the population size of a species of plant growing in a region during the years after a flood destroyed the area. Explain what the data indicate about this population.

- a. The plant population grew exponentially throughout the years as the numbers of individuals increased at an exponential rate. The population eventually became stable after reaching a maximum number of 120 individuals, which could be the carrying capacity of the environment.
- b. The population grew exponentially in the first few years and later became logistic as the rate slowed down. The population eventually became stable after reaching a maximum number of 120 individuals, which could be the carrying capacity of the local environment.
- c. The plant population grew logically throughout the years as the growth rate of the population slowed down. The population eventually became stable after reaching a maximum number of 120 individuals, which could be the carrying capacity of the environment.
- d. The population grew exponentially in the first few years and later became logistic as the rate slowed down. The population eventually became stable after reaching a number of 116 individuals, which could be the carrying capacity of the environment.

**92.** It has been suggested a population of a flowering plant is being jeopardized by population declines in a butterfly species thought to be the primary pollinator of the plant. Identify data that could best be used to either justify or refute this suggestion.

- a. nectar energy provided to the butterfly species per visit to a flower of the plant species in a field
- b. number of fruits produced per flower of plants in a section of a field screened off from access by the butterfly species
- c. number of butterfly visits per flower per day in various fields throughout the growing range of the plant
- d. species of flowers visited by individual butterflies in a field and frequency of visits to each flower species

**93.** A conservation group has claimed that the introduction of logging into a forest ecosystem will decrease the carrying capacity of trout living in a stream within the ecosystem. Describe data that could be used to either justify or refute this claim. Explain your reasoning.

- a. The growth rate of trout in the stream before and after logging will give an indication as to whether the claim is justified or not.
- b. Evaluate the death rate of trout in the stream after the introduction of logging, which will be used to justify or refute the claim.
- c. Collect data on number of trout in the stream after the introduction of logging, which will give an indication as to whether the claim is justified or not.
- d. Collect data on the number of trout in the stream before and after logging, which will give an indication as to whether the claim is justified or not.

**94.** Predict how human population change in the next 50 years is likely to affect marine ecosystems.

- a. Humans will decrease their own carrying capacity, which will also decrease the carrying capacities of marine ecosystems.
- b. Decreased fishing can be expected, which will lead to rebounds in fish populations and healthier marine ecosystems.
- c. Increases in greenhouse gas emissions are likely, with increases in ocean temperatures that trigger shifts in marine populations.
- d. Biodiversity of marine ecosystems will increase as humans use engineering to increase food production in the oceans.

**95.** Describe how the quantity of waste from human activities can be expected to change in the next 50 years and why. Explain how that change could impact a specific ecosystem.

- a. The amount of waste generated by human activities will increase exponentially as the human population continues to increase exponentially. Removal of waste would require a decrease in habitats, which will lead to decrease in populations of species dependent on those habitats.
- b. The amount of waste generated by human activities will increase exponentially as the human population continues to increase exponentially. Removal of waste will require an increase in habitats, which will lead to exponential increase in populations of species dependent on those habitats.
- c. The amount of waste generated by human activities will decrease exponentially as the human population continues to increase exponentially. Removal of waste would require an increase in habitats, which will lead to exponential increase in populations of species dependent on those habitats.
- d. The amount of waste generated by human activities will decrease exponentially as the human population continues to increase exponentially. Removal of waste will require a decrease in habitats, which will lead to decrease in populations of species dependent on those habitats.

**96.** A company wants to establish suspended cultures of mussels in a natural estuary from which they can farm mussels in a sustainable enterprise. The suspended cultures would keep the mussels contained for easy capture, but would allow free flow of estuary waters in and out of the cultures. The company wants to know the maximum number of mussels they can farm each month and maintain a sustainable system. A biologist has suggested that the limiting factor for mussels is the amount of phytoplankton that the mussels feed on. Identify data that could best be used to either justify or refute this suggestion.

- a. rates of growth of newly established mussel cultures in a lab under different phytoplankton concentrations
- b. phytoplankton population changes in the estuary as a function of intensity and duration of sunlight exposure
- c. biomasses of natural mussel populations and phytoplankton populations in the estuary determined at many different times
- d. lab measurements of phytoplankton biomass in response to added mussel population numbers

**97.** A non-venomous species of snake has a wide geographical range. In one region, the species has dull coloration and in another region, the species exhibits bright coloration that resembles a local venomous species of snake. A hypothesis has been proposed that the bright

coloration is an adaptation to defend against predation, an example of Batesian mimicry. Describe an experimental design that could be used to test this hypothesis.

- Run field tests in which dull individuals and brightly colored individuals are captured and switched into the other's territory to see how many of each survive.
  - Run field tests in which video cameras are set up to record predators capturing dull individuals and brightly colored individuals in their native territories.
  - Run laboratory tests in which predators familiar with the poisonous snake are offered dull individuals and brightly colored individuals to see if the predators show a preference.
  - Run laboratory tests in which predators familiar with the dull colored non-poisonous snake are offered poisonous brightly colored individuals and non-poisonous brightly colored individuals to see if the predators show a preference.
- 98.** Frogs are amphibians and spend time both on land and in water. Female frogs are vulnerable to predation by fish when they enter the water to lay eggs. A hypothesis has been proposed that frogs rely on chemical detection of predators in addition to visual detection. In other words, frogs detect the presence of predator fish by chemicals released by fish into the water. Design an experiment to test this hypothesis.
- Arrange containers of water in which water can be freely shared between two compartments. Fish are contained within one compartment and frogs in another such that the frogs on one side cannot see or hear fish on other side. Observe and compare the egg laying behavior of female frogs in the presence and absence of predator fish in the fish tank.
  - Arrange containers of water in which water can be freely shared between two compartments. Fish and frogs are contained within one compartment such that frogs cannot see or hear fish. Observe and compare the egg laying behavior of female frogs in the presence and absence of predator fish.
  - Arrange containers of water in which water can be freely shared between two compartments. Fish and frogs are contained within one compartment such that frogs can see or hear fish. Observe and compare the egg laying behavior of female frogs in the presence and absence of predator fish in the fish tank.
  - Arrange containers of water in which water can be freely shared between two compartments. Fish are contained within one compartment and frogs in another such that frogs on one side can see or hear fish on other side. Observe and compare the egg laying behavior of female frogs in the presence and absence of predator fish in the fish tank.

**99.**

|                   | Unspotted males | Spotted males |
|-------------------|-----------------|---------------|
| <b>1998</b>       |                 |               |
| <b>Upstream</b>   | 244             | 742           |
| <b>Downstream</b> | 368             | 1165          |
| <b>2008</b>       |                 |               |
| <b>Upstream</b>   | 298             | 791           |
| <b>Downstream</b> | 1086            | 205           |

A biologist studied two populations of the same species of a small fish living in different locations in the same tropical stream. He noticed that adult male fish were either spotted or unspotted and made careful counts of the two variants in the two stream locations in 1998. He repeated his population studies ten years later. Construct a hypothesis that accounts for these data.

- A new prey species of the fish established itself only in the downstream portion of the stream between 1998 and 2008.
- A new prey species of the fish established itself only in the upstream portion of the stream between 1998 and 2008.
- A new predator of the fish established itself only in the downstream portion of the stream between 1998 and 2008.
- A new predator of the fish established itself in both the upstream and downstream portions of the stream between 1998 and 2008.

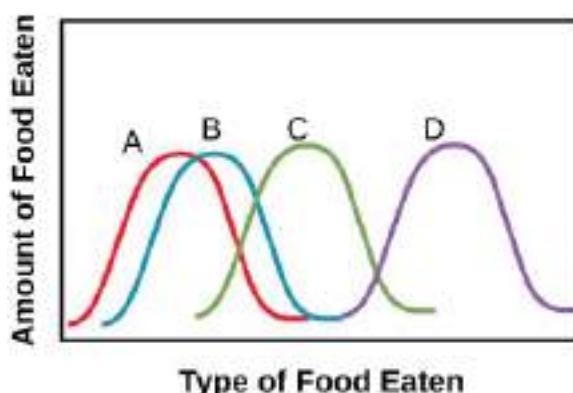

100.

| Survival Rate  |                                    |                                  |
|----------------|------------------------------------|----------------------------------|
|                | Released into mottled snail region | Released into solid snail region |
| Mottled snails | 95%                                | 5%                               |
| Solid snails   | 22%                                | 93%                              |

A species of marine snail is found in shallow waters near coastlines. This snail feeds on detritus on the ocean bottom. Researchers noticed that snails in one area had a mottled appearance, while snails in another area were solid in color. The researchers set up areas in each region for study and then released both mottled and solid snails into the solid snail region and released both mottled and solid snails into the mottled snail region. The survival rate of each variant was measured. Results are summarized in this table. Construct a possible hypothesis that accounts for these data. Explain your reasoning.

- A possible hypothesis is that the coloration of the snail is dependent on environmental conditions. Camouflage in both mottled and solid snails is best during optimum environmental conditions and does not change according to the region in which they are placed.
- A possible hypothesis is that the coloration of the snail is an adaptation in the form of camouflage to protect the snail from predators in the region it is invading. Mottled snails are best camouflaged in the solid snail region and stand out to predators and suffer greater predation when placed in their native region.
- A possible hypothesis is that the coloration of the snail is an adaptation in the form of camouflage to protect the snail from predators in its native region. Mottled snails are best camouflaged in their native region and stand out to predators and suffer greater predation when placed in the region normally occupied by solid snails.
- A possible hypothesis is that the coloration of the snail is an adaptation in the form of camouflage to protect the snail from predators in its native region. Solid snails are best camouflaged in mottled snail region and are more obvious to predators when placed in their native region.

101.

The graph summarizes data concerning four different species of lizards that inhabit tropical habitats. Predict how these species will be able to coexist if they inhabit the same region of a tropical habitat.

- a. All species will coexist with one another because they consume the same amounts of food.
- b. Species A, B, and C will best coexist because of their similarities in amount and type of food eaten.
- c. Species A and B will best coexist because they have the most overlap in diet.
- d. Species D will best coexist with any one of the other species because this species eats completely different types of food.

**102.**

|           | Insects | Nectar | Worms |
|-----------|---------|--------|-------|
| Species A | 95%     | 5%     | 0%    |
| Species B | 92%     | 3%     | 5%    |

Warblers are a group of small songbirds consisting of many species. The table summarizes data collected on the diets of two species of warblers. In addition, both species A and B use the same types of nesting materials and sites for building nests.

A biologist observes that Species A and Species B primarily inhabit different regions of a forest in western Canada. During a forest fire that wiped out the region it inhabited, Species B fled to the region inhabited by Species A. Predict what is likely to happen to these two species in the future. Explain your reasoning.

- a. Both the species will survive because of difference in needs for food and nesting space.
- b. Species A will increase in population whereas species B will remain same due to the overlapping needs for food and nesting space.
- c. Only one of these species will survive in this region due to the difference in needs for food and nesting space. The species that loses will either die off or migrate to another region.
- d. Only one of these species will survive in this region due to the overlapping needs for food and nesting space. The species that loses will either die off or migrate to another region.

**103.** Himalayan blackberries are an invasive species that has spread in the forest of the Pacific Northwest. The plants develop thick tangles of cane covered with thorns that cover ground with a tight mat. Ecologists hypothesized that Himalayan blackberries displace native species of shrubs by reproducing faster and reducing areas available for growth. They recorded the density of blackberries and native salmonberries, a native shrub, along a creek for several years. The percentage areas of ground covered by blackberries and native shrubs were

plotted over time. Based on the graph, what statement best explain the role of blackberries on the ecosystem studied?

- a. Blackberries promote the growth of salmonberry shrubs.
- b. Blackberries and salmonberry shrubs do not interfere with each other's growth.
- c. Salmonberry shrubs prevent the growth of blackberries.
- d. Blackberries displaced salmonberry shrubs.

**104.** Predict how ecosystems in the northernmost land regions will be affected by human population change in the next 50 years.

- a. Biodiversity of these northernmost regions will remain constant as humans will find other more habitable locations to house their growing numbers.
- b. The populations of organisms presently inhabiting these regions will shift as global warming causes many species to decline and new species to move in.
- c. The carrying capacity of these regions for humans will decrease as the human population increases exponentially.
- d. Ecosystems can be expected to remain untouched by humans as new technologies are developed to sustain a growing population.

**105.** A researcher is interested in investigating whether the croaking pattern produced by males in a frog species is a learned behavior or an innate behavior. Which of the following would best help the researcher answer this question?

- a. genetic analyses of adult male frogs raised in isolation and in multigenerational frog communities
- b. field observations of adult frogs in their native habitat during mating season
- c. video recordings of individual frogs raised in large multigenerational frog communities
- d. audio recordings of individual frogs at sexual maturity after being raised in total isolation

**106.** A biologist hypothesizes birds of various species recognize the predator warning calls of other bird species. The biologist has established several feeders in a forest where birds come to feed regularly. They are spread out over a wide area, making it difficult to observe all of the boxes at the same time. Describe how the biologist can use this site to collect data to test his hypothesis.

- The biologist can use video cameras to record the behavior of birds coming to the feeders.
- The biologist can leave an audio recorder near the feeders.
- The biologist can record the behavior of birds by comparing them with other birds using video cameras.
- The biologist could observe the birds continually for one month.

107.

|                             | Yellow bunting encountered and fled | Yellow bunting encountered and attacked | Total encounters |
|-----------------------------|-------------------------------------|-----------------------------------------|------------------|
| Butterflies with eyespot    | 9                                   | 19                                      | 28               |
| Butterflies without eyespot | 0                                   | 18                                      | 18               |

Yellow buntings are birds that feed on butterflies, including *Aglais urticae*, a species of butterfly that has bright circular coloring on its wing called an eyespot. Biologists have hypothesized that eyespots mimic owl eyes. Owls are predators of yellow buntings.

In laboratory experiments using yellow buntings captured from the wild and held in captivity, individual birds were observed during sessions in which they were given butterflies that had either not been treated or had been treated to remove their eyespots. Yellow buntings were scored according to whether they showed fleeing behavior when they encountered butterflies of both types. The data were compiled into a table. How do these data support the claim that one species' response to information can affect natural selection in another species?

- Comparison of the total number of encounters shows that more birds responded to the eyespot, a trait that will likely be selected against in natural populations of the butterfly.
- Comparison of the number of birds attacking butterflies with and without eyespots suggests that the presence of an eyespot makes butterflies more visible to predators resulting in selection against the trait.
- Comparison of the number of birds fleeing from butterflies with and without eyespots indicates that the eyespot trait has been disfavored because this trait makes the butterflies stand out to predators.
- Comparison of the number of birds fleeing from butterflies with and without eyespots suggests that selection has occurred in butterflies in favor of the eyespot trait, which mimics a predator of the bird.

108.

| Calls made by small bird | Call sound frequency | Small bird hearing range (1–10 kHz) | Large bird hearing range (1–4 kHz) |
|--------------------------|----------------------|-------------------------------------|------------------------------------|
| Mobbing call             | 4.5 kHz              | Yes                                 | Yes                                |
| Scolding call            | 4 kHz                | Yes                                 | Yes                                |
| Warning call             | 7–8 kHz              | Yes                                 | No                                 |

(credit: Behavioral Ecology and Sociobiology)

Biologists analyzed the sound frequencies of different calls made by a small bird species that serve as prey for a much larger predator bird species. The small bird makes three different kinds of calls: a mobbing call that a group of adults make when mobbing a single predator bird in defense of their nests, a scolding call that a single bird makes to scold a predator bird perched nearby, and a warning call that a single bird makes to warn other birds when a predator bird flies into the vicinity. A table was created to summarize the data from this analysis and also show the range of sound frequencies audible to the prey and predator species. Explain how these data support the claim that communication of information affects natural selection in the small bird species.

- a. A scolding call made by small birds can be heard by large predator birds, which is required to scold away the birds; therefore, this trait is favorable and has been naturally selected.
- b. As the mobbing call made by small birds can be heard by large predator birds, therefore small birds cannot defend their nests without the predators knowing. This unfavorable trait is thus naturally selected.
- c. The warning call made by small birds cannot be heard by large predator birds, giving the small birds an advanced warning. This is an unfavorable trait that gives birds a survival disadvantage.
- d. The warning call made by small birds cannot be heard by large predator birds, giving the small birds an advanced warning. This is a favorable trait that gives birds a survival advantage.

**109.** Which of the following statements most directly supports the claim that Monarch butterfly migration is a regulated event?

- a. Monarch butterflies fly up to 3,000 miles from their summer habitat in North America to their winter habitat in Mexico.
- b. Because the life span of a Monarch butterfly is so short, not every generation of Monarchs migrates.
- c. Monarch caterpillars feed on milkweed while adult butterflies feed on flower nectar.
- d. Changes in day length trigger hormonal and nervous system changes in Monarchs that result in behavioral changes.

**110.** What evidence can you cite to support the claim that the timing of entry into hibernation by grizzly bears is regulated? Justify why this evidence supports the claim.

- a. Grizzly bears go into hibernation at the end of winters. This observation provides evidence that there is some environmental cue that triggers physiological changes in bears.
- b. Grizzly bears do not go into hibernation at the beginning of autumn. This observation provides evidence that there is some environmental cue that triggers physiological changes in bears.
- c. Grizzly bears go into hibernation at random times during the year. This observation provides evidence that there is some environmental cue that triggers physiological changes in bears.
- d. Grizzly bears do not go into hibernation at random times during the year. This observation provides evidence that there is some environmental cue that triggers physiological changes in bears.

**111.** Some animal behaviors can be modified by

experience. Which of the following accurately predicts how an experiential factor is likely to affect an animal's behavior?

- a. A species of salmon will migrate up the same river regardless of increases in predators that visit these waterways from one year to the next.
- b. Female elk that had difficult deliveries of calves will continue to mate with males in succeeding mating seasons.
- c. Bears that receive food from humans are later more likely to break into human habitations than bears that are not approached by humans.
- d. A bird raised from an egg isolated in a lab environment will give the same alarm call as birds of the same species raised in the wild.

**112.** Estivation is a type of dormancy that some animals enter during hot, dry periods. Typically, the metabolisms of these animals slow down, their bodies retain water and some shift to altered nitrogen metabolism. Predict how the behavior of an animal such as a lizard would change in response to environmental factors that trigger the lizard into entering estivation.

- a. The lizard would sit on a rock to remain protected from predation and water loss. The breathing and heart rate would slow as it begins estivating. Then it would only do critical activities needed to sustain its living state.
- b. The lizard would live in a shaded spot to remain protected from predation and water loss. The breathing and heart rate would slow as it begins estivating. This way a lizard can perform all activities.
- c. The lizard would stay in a shaded spot to remain protected from predation and water loss. Its breathing and heart rate would slow as it begins estivating. Then it would only do critical activities needed to sustain its living state.
- d. The lizard would live in a shaded spot to remain protected from predation and water loss. The breathing and heart rate would increase as it begins estivating. Then it would only do critical activities needed to sustain its living state.

Many animals produce chemical compounds that function as alarm cues. Researchers interested in determining whether salamanders fall into this group performed the following experiment. Long-toed salamanders were captured from the wild. A few were injured and tissue from their injuries was collected and ground up with water. This solution was used to moisten a paper towel. Others were not injured and placed on moistened paper towels for 48 hours. The moistened paper towels were placed at one end of a rectangular box (stimulus end) and a paper towel moistened with water was placed at the other end (control end). In each test, a salamander was placed in the center and the researchers observed the direction in which the salamander moved. Multiple trials were performed using paper towels moistened with chemicals from injured and non-injured salamanders and the data was compiled into a table. Which of the following statements is an accurate analysis of the data?

- This salamander releases chemical compounds during injury that elicit avoidance behavior in members of its own species.
- Chemical compounds released from this salamander species during injury elicit attractant behavior in members of its own species.
- Both injured and non-injured salamanders produce chemical compounds that elicit avoidance behavior in non-injured salamanders.
- There was a significant difference between stimulus and control results from treatment involving non-injured salamanders.

114.

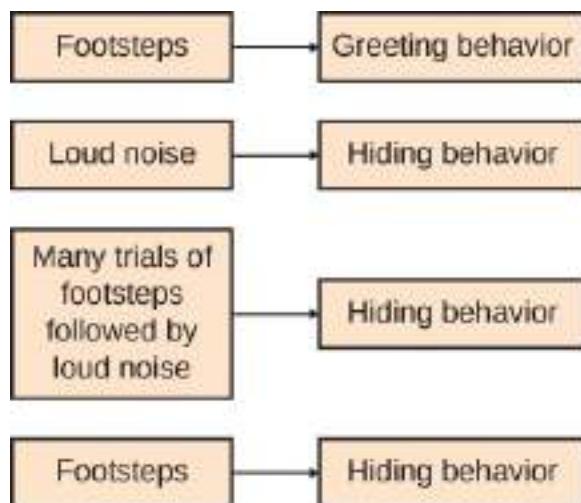

| <b>Food dispersion</b> | <b>Presence of species B</b> | <b>Number of species A giving alarm calls</b> | <b>Number of species A not giving alarm calls</b> |

(credit: Ethology)

Biologists have observed some animal species making predator warning calls when no predator is in the area. In one species of bird, for example, individuals appeared to perform this behavior as a means for deceiving other birds into fleeing from a food source that the bird making the call was then better able to access.

In investigating the possibility that this bird species uses false alarm calls to improve its access to food, the following experiment was conducted. Researchers set up a bird feeding table in a protected area to attract two species of birds, species A and B. They either clumped food in one concentrated pile on the table or dispersed the food in a much wider area under and around the table. They then observed the number of times an individual in species A gave a predator warning call when no predator was in sight as well as the presence or absence of species B at the feeding table. The data collected by the researchers are shown here. What do the data suggest about the use of deception by species A? Explain your reasoning.

- a. Species A uses deception in cases when food is plentiful, but concentrated, so access is limited to a small group of birds. A bird that had restricted access to the food has open access because of the alarm. Only in cases where it's necessary does the bird carry out this deceptive behavior.
- b. Species A uses deception in cases when food is plentiful, but concentrated, so that access is limited to a large group of birds. A bird that had restricted access to the food has open access because of the alarm. Only in cases where it's necessary does the bird carry out this deceptive behavior.
- c. Species A uses deception in cases when food is plentiful, but dispersed, so that access is limited to a small group of birds. A bird that had restricted access to the food has open access because of the alarm. Only in cases where it's necessary does the bird carry out this deceptive behavior.
- d. Species A uses deception in cases when food is plentiful, but concentrated, so that access is limited to a small group of birds. A bird that had unrestricted access to the food has open access because of the alarm. Deceptive behavior is carried out regardless of whether it is needed or not.

**115.**

This representation was created to describe how the behavior of a cat was affected as it was exposed to different stimuli. Identify the term that should be used for the process represented by this diagram.

- a. innate behavior
- b. classical conditioning
- c. operant conditioning
- d. cognitive learning

**116.** Elk migrate from summer feeding grounds in high mountain meadows down into lower valleys during winter. Using the words behavioral changes, physiological changes, seasonal changes, and migration, write the order of events that occur to bring about this migration.

- a. seasonal changes, physiological changes, migration, and behavioral changes, respectively
- b. physiological changes, seasonal changes, behavioral changes, and migration, respectively
- c. seasonal changes, behavioral changes, physiological changes, and migration, respectively
- d. seasonal changes, physiological changes, behavioral changes, and migration, respectively

**117.** Some fish swim in schools, which can respond rapidly by moving quickly away from predator threats. In schools, fish swim in a coordinated pattern without moving chaotically and bumping into one another. Which type of communication between individuals could account for the precisely coordinated movements of all of the fish in a school in response to a threat?

- a. aural signals
- b. pheromone signals
- c. tactile signals
- d. visual signals

**118.** Describe a situation in which animals of the same species exchange information in response to an approaching predator. Include a description of how the information flows between individuals.

- a. Herring gulls have a brightly colored bill. When a predator approaches, the parent gull stands over its chick and taps the bill on the ground in front of it, which elicits a begging response from a hungry chick.
- b. Prairie dogs live in underground burrows. If a look-out observes an approaching predator, they give an aural alarm cry communicating the information to the foraging individuals who then run back to safety.
- c. Herring gulls have a brightly colored bill. When a predator approaches, the parent gull stands over its nest and taps the bill on the ground, thus exchanging information of the approaching predator.
- d. Prairie dogs live inside the bark of trees. If a look-out observes an approaching predator, they give an aural alarm cry communicating the information to the foraging individuals who then run back to safety.

## SCIENCE PRACTICE CHALLENGE QUESTIONS

**119.** A flask of nutrient broth, buffered to maintain pH, is inoculated with a strain of *E. coli*. The flask is placed in a constant temperature environment where it is aerated by shaking.

A. **Predict** the effect of a change in energy availability over time.

B. **Represent** the change graphically in terms of the number of cells as a function of time.

C. In your graph as time progresses there is a change in the growth rate of the population. Add annotation to your graph to **describe** the time interval during which the growth rate is increasing linearly in proportion to the number of cells. Add annotation to your graph to **describe** another time interval during which the growth rate is decreasing in proportion to the square of the number of cells. Add a third annotation to **describe** an interval of time where the rate of growth is zero.

D. **Select and justify** two measurements of the *E. coli* population that could be made at two different points in time during growth that would be sufficient to answer questions about the population size at any time.

E. **Describe** the population of *E. coli* if the environment was continuously supplement by additional nutrient broth.

**120.** The following problem extends the Hardy-Weinberg model of population dynamics that was covered in Chapter 19. It applies mathematics that would be appropriate after a second course in Algebra. While the concept applied in this problem are within the scope of the Exam the mathematical representations are not and the item is provided to allow students who are able another look at the concepts.

The Hardy-Weinberg model of population dynamics is an algebraic representation of the relationships among genotype frequencies, F, and the probability of the dominant allele A, p, and the recessive allele a, q. The Hardy-Weinberg model of population dynamics is based on several assumptions. One of these assumptions is “random mating.” If all genes in a population are equally able to reproduce, this means that all genes are equally fit and equally fertile. Consequently, the population never evolves.

Populations do evolve and the Hardy-Weinberg model can be modified slightly to allow evolution to occur. Suppose that there is an initial population at generation zero and the probability of the dominant allele at that time is  $p_0$ . Later, at population k the probability is different. But if the frequencies of the three different combinations of alleles is known then the probabilities  $p_k$  and  $q_k$  can be calculated at generation k

$$(1) \quad p_k = F_k(AA) + \frac{1}{2}F_k(Aa) \quad q_k = F_k(aa) + \frac{1}{2}F_k(Aa)$$

And since p and q are probabilities for a case where only two alleles exist,  $p+q=1$ . Then also  $(p+q)^2=1$ , leading the

Hardy-Weinberg equation

$$p^2_k + 2p_k q_k + q^2_k = 1$$

The gene distribution never changes and  $p_k=p_{k-1}$ .

The equations of the Hardy-Weinberg model were modified (Haldane, 1924) to create a model in which evolution occurs:

(2)

$$F_k(AA) = p^2_k w_{AA} / W \quad F_k(Aa) = 2p_k q_k w_{Aa} / W \quad F_k =$$

$$q^2_k w_{aa} / W \quad W = p^2 w_{AA} + 2pqw_{Aa} + q^2 w_{aa}$$

Haldane divides by the factor  $W=F_k(AA)+F_k(Aa)+F_k(aa)$  so that the probabilities that are still calculated with equation (1) to continue to satisfy the condition for p and q to represent probabilities:  $(p+q)^2=1$ .

A. **Justify** Haldane’s model in terms of what the factors  $w_{AA}$ ,  $w_{Aa}$ , and  $w_{aa}$  mean.

B. Suppose that  $w_{AA} = w_{Aa} = 1$ , but that  $w_{aa} = 0.8$ . **Predict** what will happen to the population over time.

Fitness is determined by the environment. Moree (*The American Naturalist*, 86, 1952) measured the relative fitness in *Drosophila melanogaster* of a recessive allele that imparts black eye color as population density increases. A varying number of flies with an equal number of males and females were placed in a pint jar and progeny counted. In each experiment the population was initially heterozygous.

| Number of females x Number of males | w <sub>aa</sub> |
|-------------------------------------|-----------------|
| 1 x 1                               | 0               |
| 10 x 10                             | 0.06            |
| 50 x 50                             | 0.11            |
| 150 x 150                           | 0.46            |

Table 36.3

C. Apply Haldane’s approach to **calculate** the probability p in the first generation after mating 150 female and 150 male flies that are heterozygous using  $w_{AA} = w_{Aa} = 1$ .

Rendel (*Evolution*, 5, 1951) conducted an investigation of the dependence of fecundity (fertility) on light in ebony-eyed *D. melanogaster*. A summary of some of the data that he reported is shown in the table below:

| Fraction females inseminated |                 |                |
|------------------------------|-----------------|----------------|
| Phenotype of male            | Light condition | Dark condition |
| Ebony                        | 0.215           | 0.607          |
| Wild type                    | 0.494           | 0.466          |

**Table 36.4**

D. **Pose two scientific questions** concerning the behavioral response indicated by the data that can be tested experimentally.

E. Is there a question you can add here to wrap up this set with this LO from the list? In this case “light” is the single environmental factor, and the two phenotypes are ebony and wild type that result from different genotypes within the population of flies.

# 37 | ECOSYSTEMS

**Figure 37.1** In the southwestern United States, rainy weather causes an increase in production of pinyon nuts, causing the deer mouse population to explode. Deer mice may carry a virus called *Sin Nombre* (a hantavirus) that causes respiratory disease in humans and has a high fatality rate. In 1992–1993, wet *El Niño* weather caused a *Sin Nombre* epidemic. Navajo healers, who were aware of the link between this disease and weather, predicted the outbreak. ## Chapter Outline

- 37.1: Ecology for Ecosystems**
- 37.2: Energy Flow through Ecosystems**
- 37.3: Biogeochemical Cycles**

## Introduction

In 1993, an interesting example of ecosystem dynamics occurred when a rare lung disease struck inhabitants of the southwestern United States. This disease had an alarming rate of fatalities, killing more than half of early patients, many of whom were Native Americans. These formerly healthy young adults died from complete respiratory failure. The disease was unknown, and the Centers for Disease Control (CDC), the United States government agency responsible for managing potential epidemics, was brought in to investigate. The scientists could have learned about the disease had they known to talk with the Navajo healers who lived in the area and who had observed the connection between rainfall and mice populations, thereby predicting the 1993 outbreak.

The cause of the disease, determined within a few weeks by the CDC investigators, was the hantavirus known as *Sin Nombre*, the virus with “no name.” With insights from traditional Navajo medicine, scientists were able to characterize the disease and rapidly institute effective health measures to prevent its spread. Though not as common any more, infections from hantavirus still occur. You can read more about hantavirus in this [CDC article \(http://openstaxcollege.org/I/32hanta\)](http://openstaxcollege.org/I/32hanta).

## 37.1 | Ecology for Ecosystems

In this section, you will explore the following questions:

- What are the basic types of ecosystems on Earth?
- What are methods that ecologists use to study ecosystem structure and dynamics?
- What are the different methods of ecosystem modeling?
- What is the difference between a food chain and a food web, and what is the importance of each?

## Connection for AP® Courses

Life in an ecosystem is often about the competition for limited resources, a characteristic of the theory of natural selection. Competition in communities (all living things within a specific habitat) is observed both within species and among different species. The resources for which organisms compete include organic material from living or previously living organisms, sunlight, and mineral nutrients, which provide the energy for living processes and the matter to make up organisms' physical structures. Other critical factors influencing community dynamics are the components of its physical and geographic environment: a habitat's latitude, amount of rainfall, topography (elevation), and available species. These are all important environmental variables that determine which organisms can exist within a particular area.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 and Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

|                                   |                                                                                                                                                                                                               |
|-----------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Big Idea 2</b>                 | Biological systems utilize free energy and molecular building blocks to grow, to reproduce, and to maintain dynamic homeostasis.                                                                              |
| <b>Enduring Understanding 2.A</b> | Growth, reproduction and maintenance of living systems require free energy and matter.                                                                                                                        |
| <b>Essential Knowledge</b>        | <b>2.A.1</b> All living systems require constant input of free energy.                                                                                                                                        |
| <b>Science Practice</b>           | <b>6.4</b> The student can make claims and predictions about natural phenomena based on scientific theories and models.                                                                                       |
| <b>Learning Objective</b>         | <b>2.3</b> The student is able to predict how changes in free energy availability affect organisms, populations, and ecosystems.                                                                              |
| <b>Enduring Understanding 2.D</b> | Growth and dynamic homeostasis of a biological system are influenced by changes in the system's environment.                                                                                                  |
| <b>Essential Knowledge</b>        | <b>2.D.1</b> All biological systems from cells and organisms to populations, communities and ecosystems are affected by complex biotic and abiotic interactions involving exchange of matter and free energy. |
| <b>Science Practice</b>           | <b>5.1</b> The student can analyze data to identify patterns or relationships.                                                                                                                                |
| <b>Learning Objective</b>         | <b>2.24</b> The student is able to analyze data to identify possible patterns and relationships between a biotic or abiotic factor and a biological system, including an ecosystem.                           |
| <b>Big Idea 4</b>                 | Biological systems interact, and these systems and their interactions possess complex properties.                                                                                                             |
| <b>Enduring Understanding 4.A</b> | Interactions within biological systems lead to complex properties.                                                                                                                                            |
| <b>Essential Knowledge</b>        | <b>4.A.6</b> Interactions among living systems and with their environment result in the movement of matter and energy.                                                                                        |
| <b>Science Practice</b>           | <b>2.2</b> The student can apply mathematical routines to quantities that describe natural phenomena.                                                                                                         |
| <b>Learning Objective</b>         | <b>4.14</b> The student is able to apply mathematical routines to quantities that describe interactions among living systems and their environment, which result in the movement of matter and energy.        |
| <b>Essential Knowledge</b>        | <b>4.A.6</b> Interactions among living systems and with their environment result in the movement of matter and energy.                                                                                        |

|                            |                                                                                                                                                                                                                                                 |

| <b>Science Practice</b>    | <b>1.4</b> The student can use representations and models to analyze situations or solve problems qualitatively and quantitatively.                                                                                                             |
| <b>Learning Objective</b>  | <b>4.15</b> The student is able to use visual representations to analyze situations or solve problems qualitatively to illustrate how interactions among living systems and with their environment result in the movement of matter and energy. |
| <b>Essential Knowledge</b> | <b>4.A.6</b> Interactions among living systems and with their environment result in the movement of matter and energy.                                                                                                                          |
| <b>Science Practice</b>    | <b>6.4</b> The student can make claims and predictions about natural phenomena based on scientific theories and models.                                                                                                                         |
| <b>Learning Objective</b>  | <b>4.16</b> The student is able to predict the effects of a change of matter or energy availability on communities and ecosystems.                                                                                                              |

An **ecosystem** is a community of living organisms and their interactions with their abiotic (non-living) environment. Ecosystems can be small, such as the tide pools found near the rocky shores of many oceans, or large, such as the Amazon Rainforest in Brazil ([Figure 37.2](#)).

**Figure 37.2** A (a) tidal pool ecosystem in Matinicus Island in Maine is a small ecosystem, while the (b) Amazon Rainforest in Brazil is a large ecosystem. (credit a: modification of work by "takomabibelot"/Flickr; credit b: modification of work by Ivan Mlinaric)

There are three broad categories of ecosystems based on their general environment: freshwater, ocean water, and terrestrial. Within these broad categories are individual ecosystem types based on the organisms present and the type of environmental habitat.

Ocean ecosystems are the most common, comprising 75 percent of the Earth's surface and consisting of three basic types: shallow ocean, deep ocean water, and deep ocean surfaces (the low depth areas of the deep oceans). The shallow ocean ecosystems include extremely biodiverse coral reef ecosystems, and the deep ocean surface is known for its large numbers of plankton and krill (small crustaceans) that support it. These two environments are especially important to aerobic respirators worldwide as the phytoplankton perform 40 percent of all photosynthesis on Earth. Although not as diverse as the other two, deep ocean ecosystems contain a wide variety of marine organisms. Such ecosystems exist even at the bottom of the ocean where light is unable to penetrate through the water.

Freshwater ecosystems are the rarest, occurring on only 1.8 percent of the Earth's surface. Lakes, rivers, streams, and springs comprise these systems; they are quite diverse, and they support a variety of fish, amphibians, reptiles, insects, phytoplankton, fungi, and bacteria.

Terrestrial ecosystems, also known for their diversity, are grouped into large categories called biomes, such as tropical rain forests, savannas, deserts, coniferous forests, deciduous forests, and tundra. Grouping these ecosystems into just a few biome categories obscures the great diversity of the individual ecosystems within them. For example, there is great variation in desert vegetation: the saguaro cacti and other plant life in the Sonoran Desert, in the United States, are relatively abundant compared to the desolate rocky desert of Boa Vista, an island off the coast of Western Africa ([Figure 37.3](#)).

**Figure 37.3** Desert ecosystems, like all ecosystems, can vary greatly. The desert in (a) Saguaro National Park, Arizona, has abundant plant life, while the rocky desert of (b) Boa Vista island, Cape Verde, Africa, is devoid of plant life. (credit a: modification of work by Jay Galvin; credit b: modification of work by Ingo Wölbern)

Ecosystems are complex with many interacting parts. They are routinely exposed to various disturbances, or changes in the environment that effect their compositions: yearly variations in rainfall and temperature and the slower processes of plant growth, which may take several years. Many of these disturbances are a result of natural processes. For example, when lightning causes a forest fire and destroys part of a forest ecosystem, the ground is eventually populated by grasses, then by bushes and shrubs, and later by mature trees, restoring the forest to its former state. The impact of environmental disturbances caused by human activities is as important as the changes wrought by natural processes. Human agricultural practices, air pollution, acid rain, global deforestation, overfishing, eutrophication, oil spills, and illegal dumping on land and into the ocean are all issues of concern to conservationists.

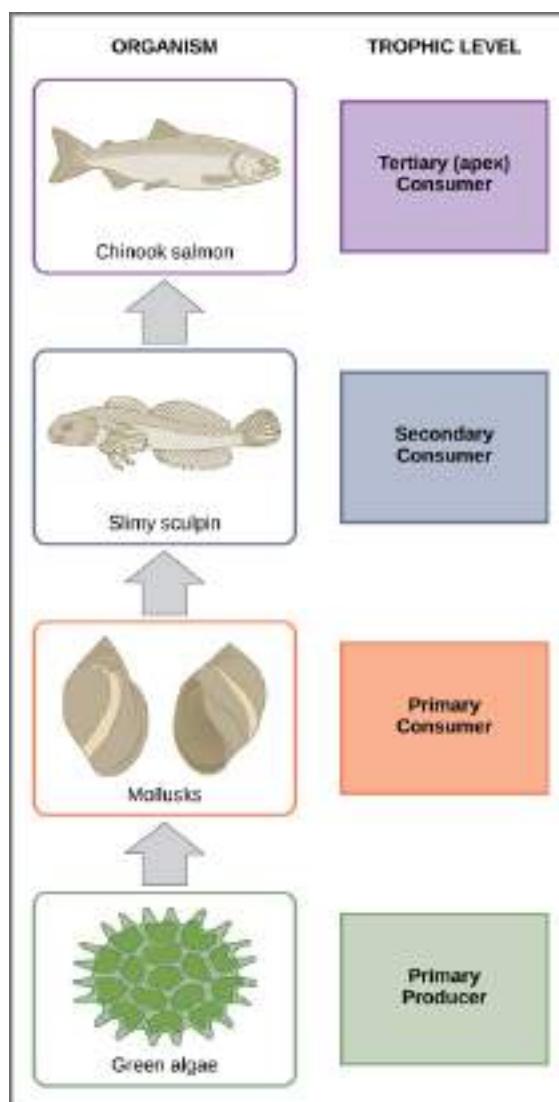

**Equilibrium** is the steady state of an ecosystem where all organisms are in balance with their environment and with each other. In ecology, two parameters are used to measure changes in ecosystems: resistance and resilience. The ability of an ecosystem to remain at equilibrium in spite of disturbances is called **resistance**. The speed at which an ecosystem recovers equilibrium after being disturbed, called its **resilience**. Ecosystem resistance and resilience are especially important when considering human impact. The nature of an ecosystem may change to such a degree that it can lose its resilience entirely. This process can lead to the complete destruction or irreversible altering of the ecosystem.

## Food Chains and Food Webs

The term “food chain” is sometimes used metaphorically to describe human social situations. In this sense, food chains are thought of as a competition for survival, such as “who eats whom?” Someone eats and someone is eaten. Therefore, it is not surprising that in our competitive “dog-eat-dog” society, individuals who are considered successful are seen as being at the top of the food chain, consuming all others for their benefit, whereas the less successful are seen as being at the bottom.

The scientific understanding of a food chain is more precise than in its everyday usage. In ecology, a **food chain** is a linear sequence of organisms through which nutrients and energy pass: primary producers, primary consumers, and higher-level consumers are used to describe ecosystem structure and dynamics. There is a single path through the chain. Each organism in a food chain occupies what is called a **trophic level**. Depending on their role as producers or consumers, species or groups of species can be assigned to various trophic levels.

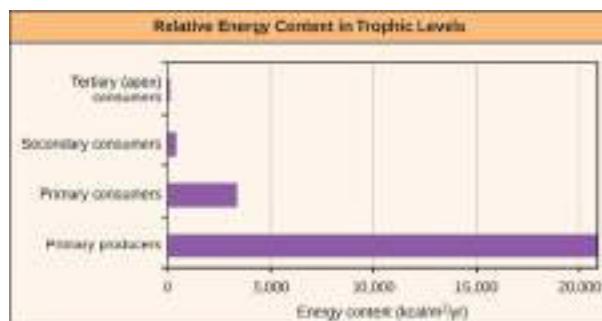

In many ecosystems, the bottom of the food chain consists of photosynthetic organisms (plants and/or phytoplankton), which are called **primary producers**. The organisms that consume the primary producers are herbivores: the **primary consumers**. **Secondary consumers** are usually carnivores that eat the primary consumers. **Tertiary consumers** are carnivores that eat other carnivores. Higher-level consumers feed on the next lower trophic levels, and so on, up to the organisms at the top of the food chain: the **apex consumers**. In the Lake Ontario food chain shown in **Figure 37.4**, the Chinook salmon is the apex consumer at the top of this food chain.

**Figure 37.4** These are the trophic levels of a food chain in Lake Ontario at the United States-Canada border. Energy and nutrients flow from photosynthetic green algae at the bottom to the top of the food chain: the Chinook salmon.

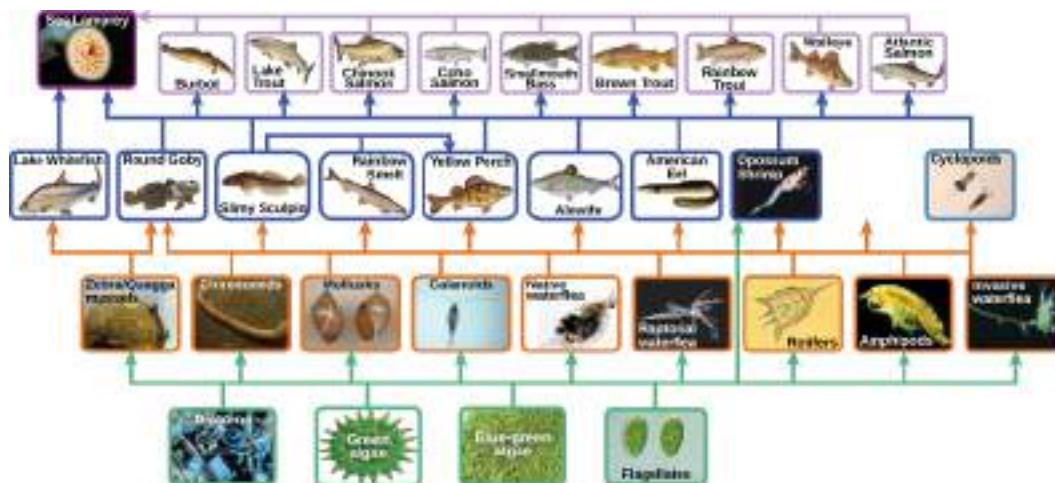

One major factor that limits the length of food chains is energy. Energy is lost as heat between each trophic level due to the second law of thermodynamics. Thus, after a limited number of trophic energy transfers, the amount of energy remaining in the food chain may not be great enough to support viable populations at yet a higher trophic level.

The loss of energy between trophic levels is illustrated by the pioneering studies of Howard T. Odum in the Silver Springs, Florida, ecosystem in the 1940s (**Figure 37.5**). The primary producers generated 20,819 kcal/m<sup>2</sup>/yr (kilocalories per square meter per year), the primary consumers generated 3368 kcal/m<sup>2</sup>/yr, the secondary consumers generated 383 kcal/m<sup>2</sup>/yr, and the tertiary consumers only generated 21 kcal/m<sup>2</sup>/yr. Thus, there is little energy remaining for another level of consumers in this ecosystem.

**Figure 37.5** The relative energy in trophic levels in a Silver Springs, Florida, ecosystem is shown. Each trophic level has less energy available and supports fewer organisms at the next level.

There is a problem when using food chains to accurately describe most ecosystems. Even when all organisms are grouped into appropriate trophic levels, some of these organisms can feed on species from more than one trophic level; likewise, some of these organisms can be eaten by species from multiple trophic levels. In other words, the linear model of ecosystems, the food chain, is not completely descriptive of ecosystem structure. A holistic model—which accounts for all the interactions between different species and their complex interconnected relationships with each other and with the environment—is a more accurate and descriptive model for ecosystems. A **food web** is a graphic representation of a holistic, non-linear web of primary producers, primary consumers, and higher-level consumers used to describe ecosystem structure and dynamics (Figure 37.6).

**Figure 37.6** This food web shows the interactions between organisms across trophic levels in the Lake Ontario ecosystem. Primary producers are outlined in green, primary consumers in orange, secondary consumers in blue, and tertiary (apex) consumers in purple. Arrows point from an organism that is consumed to the organism that consumes it. Notice how some lines point to more than one trophic level. For example, the opossum shrimp eats both primary producers and primary consumers. (credit: NOAA, GLERL)

A comparison of the two types of structural ecosystem models shows strength in both. Food chains are more flexible for analytical modeling, are easier to follow, and are easier to experiment with, whereas food web models more accurately represent ecosystem structure and dynamics, and data can be directly used as input for simulation modeling.

Head to this **online interactive simulator** ([http://openstaxcollege.org/l/food\\_web](http://openstaxcollege.org/l/food_web)) to investigate food web function. In the *Interactive Labs* box, under Food Web, click **Step 1**. Read the instructions first, and then click **Step 2** for additional instructions. When you are ready to create a simulation, in the upper-right corner of the *Interactive Labs* box, click **OPEN SIMULATOR**.

What happens to a food web in the absence of primary producers such as plants? Why?

- a. A food web will be produced, but position of some organisms will vary in the food web as their diet will vary.
- b. Some primary consumers will perform the function of primary producers in the food web or chain.
- c. A food web is unable to be produced as there is no basal energy source for consumers to obtain energy from.
- d. A food web is unable to be produced because very less amount of basal energy source is available for consumers to obtain energy from.

Two general types of food webs are often shown interacting within a single ecosystem. A **grazing food web** (such as the Lake Ontario food web in [Figure 37.6](#)) has plants or other photosynthetic organisms at its base, followed by herbivores and various carnivores. A **detrital food web** consists of a base of organisms that feed on decaying organic matter (dead organisms), called decomposers or detritivores. These organisms are usually bacteria or fungi that recycle organic material back into the biotic part of the ecosystem as they themselves are consumed by other organisms. As all ecosystems require a method to recycle material from dead organisms, most grazing food webs have an associated detrital food web. For example, in a meadow ecosystem, plants may support a grazing food web of different organisms, primary and other levels of consumers, while at the same time supporting a detrital food web of bacteria, fungi, and detritivorous invertebrates feeding off dead plants and animals.

# evolution CONNECTION

## Three-spined Stickleback

It is well established by the theory of natural selection that changes in the environment play a major role in the evolution of species within an ecosystem. However, little is known about how the evolution of species within an ecosystem can alter the ecosystem environment. In 2009, Dr. Luke Harmon, from the University of Idaho in Moscow, published a paper that for the first time showed that the evolution of organisms into subspecies can have direct effects on their ecosystem environment.<sup>[1]</sup>

The three-spined stickleback (*Gasterosteus aculeatus*) is a freshwater fish that evolved from a saltwater fish to live in freshwater lakes about 10,000 years ago, which is considered a recent development in evolutionary time (Figure 37.7). Over the last 10,000 years, these freshwater fish then became isolated from each other in different lakes. Depending on which lake population was studied, findings showed that these sticklebacks then either remained as one species or evolved into two species. The divergence of species was made possible by their use of different areas of the pond for feeding called micro niches.

Dr. Harmon and his team created artificial pond microcosms in 250-gallon tanks and added muck from freshwater ponds as a source of zooplankton and other invertebrates to sustain the fish. In different experimental tanks they introduced one species of stickleback from either a single-species or double-species lake.

Over time, the team observed that some of the tanks bloomed with algae while others did not. This puzzled the scientists, and they decided to measure the water's dissolved organic carbon (DOC), which consists of mostly large molecules of decaying organic matter that give pond-water its slightly brownish color. It turned out that the water from the tanks with two-species fish contained larger particles of DOC (and hence darker water) than water with single-species fish. This increase in DOC blocked the sunlight and prevented algal blooming. Conversely, the water from the single-species tank contained smaller DOC particles, allowing more sunlight penetration to fuel the algal blooms.

This change in the environment, which is due to the different feeding habits of the stickleback species in each lake type, probably has a great impact on the survival of other species in these ecosystems, especially other photosynthetic organisms. Thus, the study shows that, at least in these ecosystems, the environment and the evolution of populations have reciprocal effects that may now be factored into simulation models.

**Figure 37.7** The three-spined stickleback evolved from a saltwater fish to freshwater fish. (credit: Barrett Paul, USFWS)

In the lake microcosms, why were algal blooms possible in the presence of one, but not two stickleback species?

- a. Because there were larger molecules of dissolved organic content in the presence of two species versus one species.
- b. Because two stickleback species consume all of the nutrients required by the algae to bloom.
- c. Because one species had more dissolved organic matter available in their habitat than the other species.
- d. Because more algae is consumed in the presence of two stickleback species versus only one species.

## Research into Ecosystem Dynamics: Ecosystem Experimentation and Modeling

The study of the changes in ecosystem structure caused by changes in the environment (disturbances) or by internal forces is called **ecosystem dynamics**. Ecosystems are characterized using a variety of research methodologies. Some ecologists study ecosystems using controlled experimental systems, while some study entire ecosystems in their natural state, and others use both approaches.

A **holistic ecosystem model** attempts to quantify the composition, interaction, and dynamics of entire ecosystems; it is the most representative of the ecosystem in its natural state. A food web is an example of a holistic ecosystem model. However, this type of study is limited by time and expense, as well as the fact that it is neither feasible nor ethical to do experiments on large natural ecosystems. To quantify all different species in an ecosystem and the dynamics in their habitat is difficult, especially when studying large habitats such as the Amazon Rainforest, which covers 1.4 billion acres (5.5 million km<sup>2</sup>) of the Earth's surface.

For these reasons, scientists study ecosystems under more controlled conditions. Experimental systems usually involve either partitioning a part of a natural ecosystem that can be used for experiments, termed a **mesocosm**, or by re-creating an ecosystem entirely in an indoor or outdoor laboratory environment, which is referred to as a **microcosm**. A major limitation to these approaches is that removing individual organisms from their natural ecosystem or altering a natural ecosystem through partitioning may change the dynamics of the ecosystem. These changes are often due to differences in species numbers and diversity and also to environment alterations caused by partitioning (mesocosm) or re-creating (microcosm) the natural habitat. Thus, these types of experiments are not totally predictive of changes that would occur in the ecosystem from which they were gathered.

As both of these approaches have their limitations, some ecologists suggest that results from these experimental systems should be used only in conjunction with holistic ecosystem studies to obtain the most representative data about ecosystem structure, function, and dynamics.

Scientists use the data generated by these experimental studies to develop ecosystem models that demonstrate the structure and dynamics of ecosystems. Three basic types of ecosystem modeling are routinely used in research and ecosystem management: a conceptual model, an analytical model, and a simulation model. A **conceptual model** is an ecosystem model that consists of flow charts to show interactions of different compartments of the living and nonliving components of the ecosystem. A conceptual model describes ecosystem structure and dynamics and shows how environmental disturbances affect the ecosystem; however, its ability to predict the effects of these disturbances is limited. Analytical and simulation models, in contrast, are mathematical methods of describing ecosystems that are indeed capable of predicting the effects of potential environmental changes without direct experimentation, although with some limitations as to accuracy. An **analytical model** is an ecosystem model that is created using simple mathematical formulas to predict the effects of environmental disturbances on ecosystem structure and dynamics. A **simulation model** is an ecosystem model that is created using complex computer algorithms to holistically model ecosystems and to predict the effects of environmental disturbances on ecosystem structure and dynamics. Ideally, these models are accurate enough to determine which components of the ecosystem are particularly sensitive to disturbances, and they can serve as a guide to ecosystem managers (such as conservation ecologists or fisheries biologists) in the practical maintenance of ecosystem health.

### **Conceptual Models**

Conceptual models are useful for describing ecosystem structure and dynamics and for demonstrating the relationships between different organisms in a community and their environment. Conceptual models are usually depicted graphically as flow charts. The organisms and their resources are grouped into specific compartments with arrows showing the relationship and transfer of energy or nutrients between them. Thus, these diagrams are sometimes called compartment models.

To model the cycling of mineral nutrients, organic and inorganic nutrients are subdivided into those that are bioavailable (ready to be incorporated into biological macromolecules) and those that are not. For example, in a terrestrial ecosystem near a deposit of coal, carbon will be available to the plants of this ecosystem as carbon dioxide gas in a short-term period, not from the carbon-rich coal itself. However, over a longer period, microorganisms capable of digesting coal will incorporate its carbon or release it as natural gas (methane, CH<sub>4</sub>), changing this unavailable organic source into an available one. This conversion is greatly accelerated by the combustion of fossil fuels by humans, which releases large amounts of carbon dioxide into the atmosphere. This is thought to be a major factor in the rise of the atmospheric carbon dioxide levels in the industrial age. The carbon dioxide released from burning fossil fuels is produced faster than photosynthetic organisms can use it. This process is intensified by the reduction of photosynthetic trees because of worldwide deforestation. Most scientists agree that high atmospheric carbon dioxide is a major cause of global climate change.

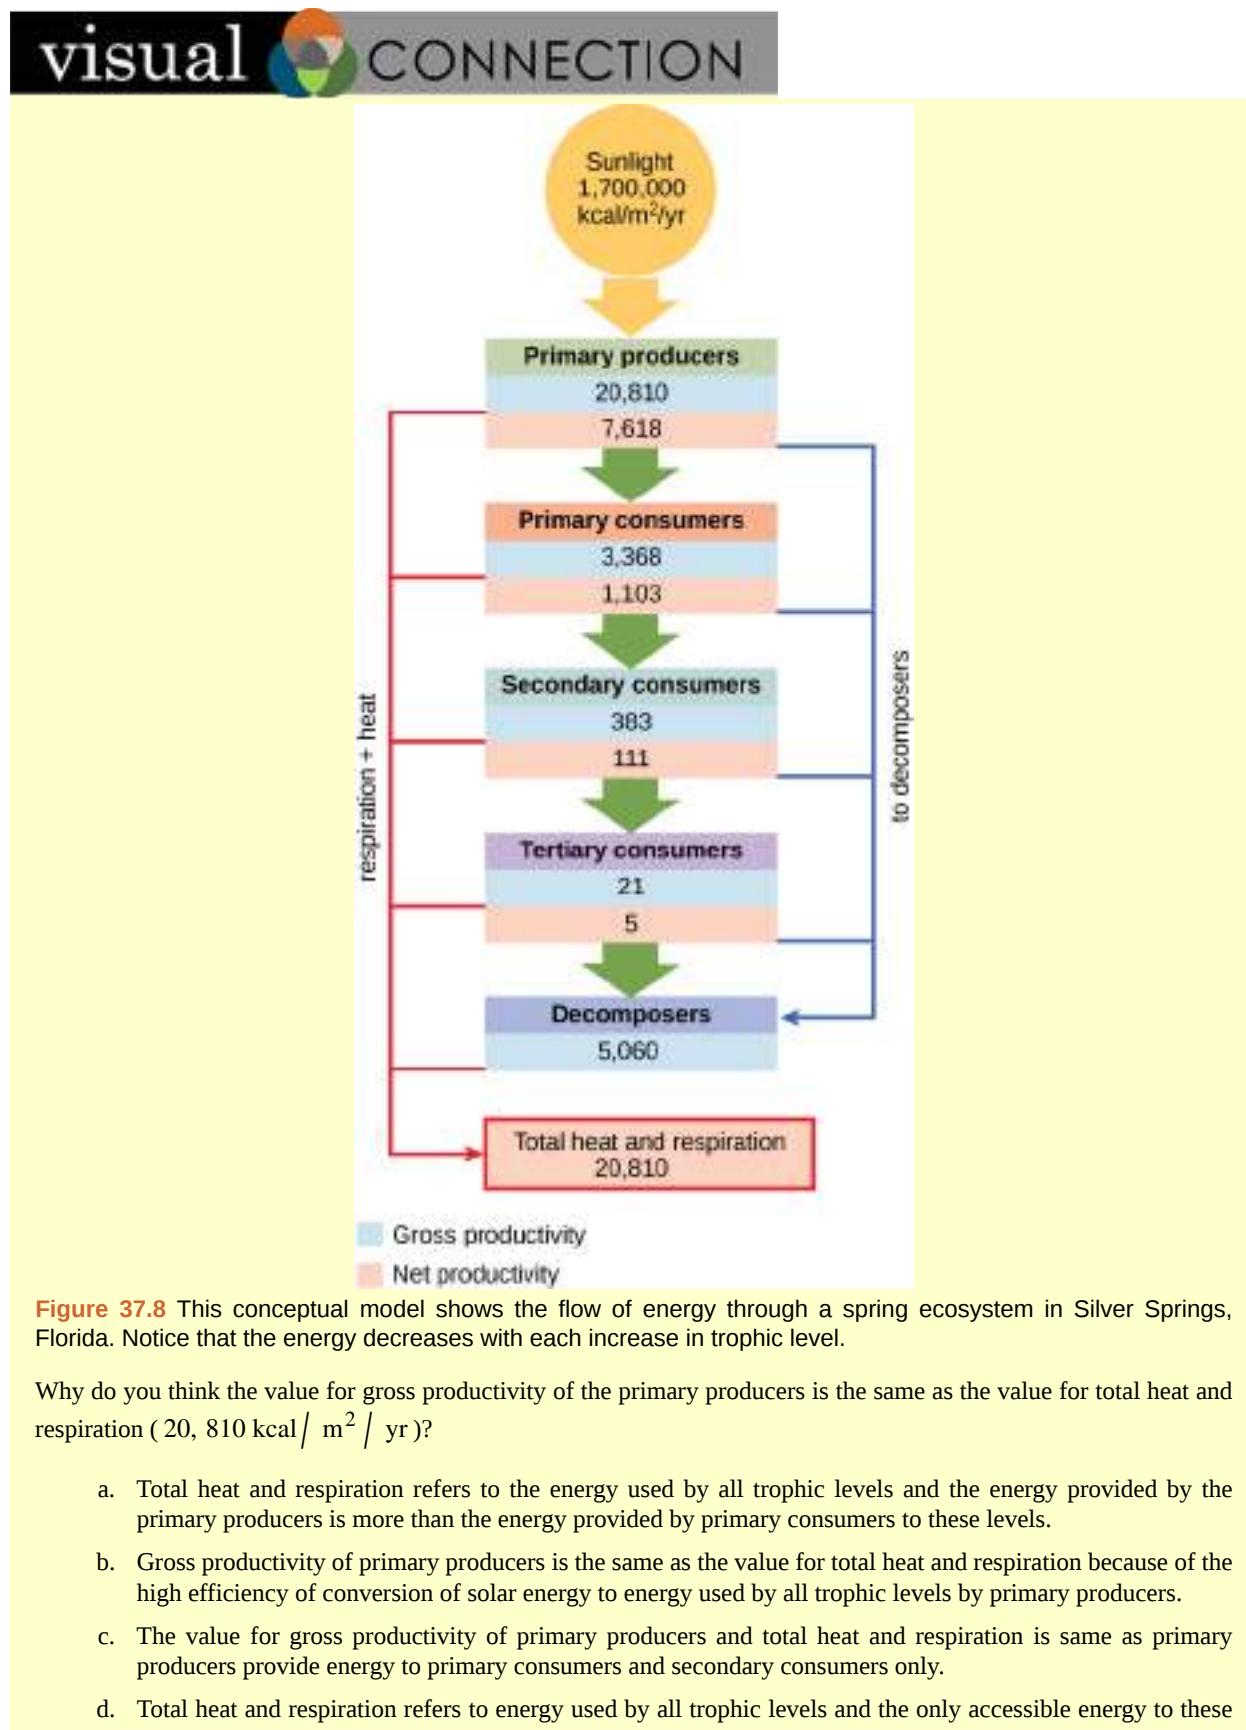

Conceptual models are also used to show the flow of energy through particular ecosystems. **Figure 37.8** is based on Howard

1. *Nature* (Vol. 458, April 1, 2009)

T. Odum's classical study of the Silver Springs, Florida, holistic ecosystem in the mid-twentieth century.<sup>[2]</sup> This study shows the energy content and transfer between various ecosystem compartments.

---

2. Howard T. Odum, "Trophic Structure and Productivity of Silver Springs, Florida," *Ecological Monographs* 27, no. 1 (1957): 47–112.

**Figure 37.8** This conceptual model shows the flow of energy through a spring ecosystem in Silver Springs, Florida. Notice that the energy decreases with each increase in trophic level.

Why do you think the value for gross productivity of the primary producers is the same as the value for total heat and respiration ( $20,810 \text{ kcal/m}^2/\text{yr}$ )?

- Total heat and respiration refers to the energy used by all trophic levels and the energy provided by the primary producers is more than the energy provided by primary consumers to these levels.
- Gross productivity of primary producers is the same as the value for total heat and respiration because of the high efficiency of conversion of solar energy to energy used by all trophic levels by primary producers.
- The value for gross productivity of primary producers and total heat and respiration is same as primary producers provide energy to primary consumers and secondary consumers only.
- Total heat and respiration refers to energy used by all trophic levels and the only accessible energy to these

levels is provided by primary producers.

### Analytical and Simulation Models

The major limitation of conceptual models is their inability to predict the consequences of changes in ecosystem species and/or environment. Ecosystems are dynamic entities and subject to a variety of abiotic and biotic disturbances caused by natural forces and/or human activity. Ecosystems altered from their initial equilibrium state can often recover from such disturbances and return to a state of equilibrium. As most ecosystems are subject to periodic disturbances and are often in a state of change, they are usually either moving toward or away from their equilibrium state. There are many of these equilibrium states among the various components of an ecosystem, which affects the ecosystem overall. Furthermore, as humans have the ability to greatly and rapidly alter the species content and habitat of an ecosystem, the need for predictive models that enable understanding of how ecosystems respond to these changes becomes more crucial.

Analytical models often use simple, linear components of ecosystems, such as food chains, and are known to be complex mathematically; therefore, they require a significant amount of mathematical knowledge and expertise. Although analytical models have great potential, their simplification of complex ecosystems is thought to limit their accuracy. Simulation models that use computer programs are better able to deal with the complexities of ecosystem structure.

A recent development in simulation modeling uses supercomputers to create and run individual-based simulations, which accounts for the behavior of individual organisms and their effects on the ecosystem as a whole. These simulations are considered to be the most accurate and predictive of the complex responses of ecosystems to disturbances.

Visit [The Darwin Project](http://openstaxcollege.org/l/Darwin_project) ([http://openstaxcollege.org/l/Darwin\\_project](http://openstaxcollege.org/l/Darwin_project)) to view a variety of ecosystem models.

Why doesn't an increased number of prey species in marine ecosystems lead to maximal feeding of predators?

- Because there may not be enough predators that can eat each of the prey species.
- Non-maximal feeding of predators occurs due to inadequate dispersal of prey species in the marine ecosystems.
- Non maximal feeding of predators may occur due to the presence of new prey species with effective defenses that are inherited.
- Because of natural selection, non-maximal feeding of predators occurs.

### Activity

Investigate a food web in an aquatic or terrestrial ecosystem of your choice, for example, coral reef. Create a diagram of the food web and describe the role of each organism in the web. Then arbitrarily remove one organism from the food web and predict how this will affect the ecosystem with respect to the movement of matter and energy. Put that organism back in your food web and remove a different organism. Predict how the ecosystem will be affected. Was your prediction the same as it was for the first organism?

### Think About It

What are the differences and similarities between food chains and food webs? How are both used to describe an ecosystem with respect to the movement of matter and energy through the ecosystem?

## 37.2 | Energy Flow through Ecosystems

In this section, you will explore the following questions:

- How do organisms acquire energy in a food web and associated food chains?
- How does the efficiency of energy transfer between trophic levels affect ecosystem structure and dynamics?
- What are the characteristics of each trophic level in an ecosystem, and how can ecological pyramids be used to model them?

### Connection for AP<sup>®</sup> Courses

As we learned when we explored concepts in earlier chapters, all living organisms require energy in one form or another, usually ATP, to carry out cellular processes. It is important to understand how organisms in an ecosystem acquire free energy and how that energy is passed among organisms through food webs and their constituent food chains. Energy takes a one-way path through ecosystems because energy conversions result in a loss of usable (free) energy through the release of heat. In addition, matter cycles and recycles as it moves from organism to organism. We also have learned that the biotic and abiotic components of an ecosystem interact. Autotrophs, chemoautotrophs, heterotrophs and decomposers comprise the living components, whereas abiotic factors include nutrients, temperature, pH, availability of sunlight, and type of soil. In this section, a variety of ways to depict this movement of energy through an ecosystem will be presented. Utilizing multiple representations of data as well as understanding the movement of matter and energy through systems are significant concepts in the AP<sup>®</sup> Biology course.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 4 of the AP<sup>®</sup> Biology Curriculum Framework. The AP<sup>®</sup> Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP<sup>®</sup> Biology course, an inquiry-based laboratory experience, instructional activities, and AP<sup>®</sup> exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Learning Objective</b>  | <b>4.15</b> The student is able to use visual representations to analyze situations or solve problems qualitatively to illustrate how interactions among living systems and with their environment result in the movement of matter and energy. |

All living things require energy in one form or another. Energy is required by most complex metabolic pathways (often in the form of adenosine triphosphate, ATP), especially those responsible for building large molecules from smaller compounds, and life itself is an energy-driven process. Living organisms would not be able to assemble macromolecules (proteins, lipids, nucleic acids, and complex carbohydrates) from their monomeric subunits without a constant energy input.

It is important to understand how organisms acquire energy and how that energy is passed from one organism to another through food webs and their constituent food chains. Food webs illustrate how energy flows directionally through ecosystems, including how efficiently organisms acquire it, use it, and how much remains for use by other organisms of the food web.

## How Organisms Acquire Energy in a Food Web

Energy is acquired by living things in three ways: photosynthesis, chemosynthesis, and the consumption and digestion of other living or previously living organisms by heterotrophs.

Photosynthetic and chemosynthetic organisms are both grouped into a category known as autotrophs: organisms capable of synthesizing their own food (more specifically, capable of using inorganic carbon as a carbon source). Photosynthetic autotrophs (photoautotrophs) use sunlight as an energy source, whereas chemosynthetic autotrophs (chemoautotrophs) use inorganic molecules as an energy source. Autotrophs are critical for all ecosystems. Without these organisms, energy would not be available to other living organisms and life itself would not be possible.

Photoautotrophs, such as plants, algae, and photosynthetic bacteria, serve as the energy source for a majority of the world's ecosystems. These ecosystems are often described by grazing food webs. Photoautotrophs harness the solar energy of the sun by converting it to chemical energy in the form of ATP (and NADP). The energy stored in ATP is used to synthesize complex organic molecules, such as glucose.

**Chemoautotrophs** are primarily bacteria that are found in rare ecosystems where sunlight is not available, such as in those associated with dark caves or hydrothermal vents at the bottom of the ocean (**Figure 37.9**). Many chemoautotrophs in hydrothermal vents use hydrogen sulfide ( $H_2S$ ), which is released from the vents as a source of chemical energy. This allows chemoautotrophs to synthesize complex organic molecules, such as glucose, for their own energy and in turn supplies energy to the rest of the ecosystem.

**Figure 37.9** Swimming shrimp, a few squat lobsters, and hundreds of vent mussels are seen at a hydrothermal vent at the bottom of the ocean. As no sunlight penetrates to this depth, the ecosystem is supported by chemoautotrophic bacteria and organic material that sinks from the ocean's surface. This picture was taken in 2006 at the submerged NW Eifuku volcano off the coast of Japan by the National Oceanic and Atmospheric Administration (NOAA). The summit of this highly active volcano lies 1535 m below the surface.

## Productivity within Trophic Levels

Productivity within an ecosystem can be defined as the percentage of energy entering the ecosystem incorporated into biomass in a particular trophic level. **Biomass** is the total mass, in a unit area at the time of measurement, of living or previously living organisms within a trophic level. Ecosystems have characteristic amounts of biomass at each trophic level. For example, in the English Channel ecosystem the primary producers account for a biomass of  $4 \text{ g/m}^2$  (grams per meter squared), while the primary consumers exhibit a biomass of  $21 \text{ g/m}^2$ .

The productivity of the primary producers is especially important in any ecosystem because these organisms bring energy to other living organisms by photoautotrophy or chemoautotrophy. The rate at which photosynthetic primary producers incorporate energy from the sun is called **gross primary productivity**. An example of gross primary productivity is shown in the compartment diagram of energy flow within the Silver Springs aquatic ecosystem as shown ([Figure 37.8](#)). In this ecosystem, the total energy accumulated by the primary producers (gross primary productivity) was shown to be  $20,810 \text{ kcal/m}^2/\text{yr}$ .

Because all organisms need to use some of this energy for their own functions (like respiration and resulting metabolic heat loss) scientists often refer to the net primary productivity of an ecosystem. **Net primary productivity** is the energy that remains in the primary producers after accounting for the organisms' respiration and heat loss. The net productivity is then available to the primary consumers at the next trophic level. In our Silver Spring example, 13,187 of the  $20,810 \text{ kcal/m}^2/\text{yr}$  were used for respiration or were lost as heat, leaving  $7,632 \text{ kcal/m}^2/\text{yr}$  of energy for use by the primary consumers.

## Ecological Efficiency: The Transfer of Energy between Trophic Levels

As illustrated in [Figure 37.8](#), large amounts of energy are lost from the ecosystem from one trophic level to the next level as energy flows from the primary producers through the various trophic levels of consumers and decomposers. The main reason for this loss is the second law of thermodynamics, which states that whenever energy is converted from one form to another, there is a tendency toward disorder (entropy) in the system. In biologic systems, this means a great deal of energy is lost as metabolic heat when the organisms from one trophic level consume the next level. In the Silver Springs ecosystem example ([Figure 37.8](#)), we see that the primary consumers produced  $1103 \text{ kcal/m}^2/\text{yr}$  from the  $7618 \text{ kcal/m}^2/\text{yr}$  of energy available to them from the primary producers. The measurement of energy transfer efficiency between two successive trophic levels is termed the **trophic level transfer efficiency (TLTE)** and is defined by the formula:

$$\text{TLTE} = \frac{\text{production at present trophic level}}{\text{production at previous trophic level}} \times 100$$

In Silver Springs, the TLTE between the first two trophic levels was approximately 14.8 percent. The low efficiency of energy transfer between trophic levels is usually the major factor that limits the length of food chains observed in a food

web. The fact is, after four to six energy transfers, there is not enough energy left to support another trophic level. In the Lake Ontario example shown in **Ecology of Ecosystems**, only three energy transfers occurred between the primary producer, (green algae), and the apex consumer (Chinook salmon).

Ecologists have many different methods of measuring energy transfers within ecosystems. Some transfers are easier or more difficult to measure depending on the complexity of the ecosystem and how much access scientists have to observe the ecosystem. In other words, some ecosystems are more difficult to study than others, and sometimes the quantification of energy transfers has to be estimated.

Another main parameter that is important in characterizing energy flow within an ecosystem is the net production efficiency. **Net production efficiency (NPE)** allows ecologists to quantify how efficiently organisms of a particular trophic level incorporate the energy they receive into biomass; it is calculated using the following formula:

$$\text{NPE} = \frac{\text{net consumer productivity}}{\text{assimilation}} \times 100$$

**Net consumer productivity** is the energy content available to the organisms of the next trophic level. **Assimilation** is the biomass (energy content generated per unit area) of the present trophic level after accounting for the energy lost due to incomplete ingestion of food, energy used for respiration, and energy lost as waste. Incomplete ingestion refers to the fact that some consumers eat only a part of their food. For example, when a lion kills an antelope, it will eat everything except the hide and bones. The lion is missing the energy-rich bone marrow inside the bone, so the lion does not make use of all the calories its prey could provide.

Thus, NPE measures how efficiently each trophic level uses and incorporates the energy from its food into biomass to fuel the next trophic level. In general, cold-blooded animals (ectotherms), such as invertebrates, fish, amphibians, and reptiles, use less of the energy they obtain for respiration and heat than warm-blooded animals (endotherms), such as birds and mammals. The extra heat generated in endotherms, although an advantage in terms of the activity of these organisms in colder environments, is a major disadvantage in terms of NPE. Therefore, many endotherms have to eat more often than ectotherms to get the energy they need for survival. In general, NPE for ectotherms is an order of magnitude (10x) higher than for endotherms. For example, the NPE for a caterpillar eating leaves has been measured at 18 percent, whereas the NPE for a squirrel eating acorns may be as low as 1.6 percent.

The inefficiency of energy use by warm-blooded animals has broad implications for the world's food supply. It is widely accepted that the meat industry uses large amounts of crops to feed livestock, and because the NPE is low, much of the energy from animal feed is lost. For example, it costs about \$0.01 to produce 1000 dietary calories (kcal) of corn or soybeans, but approximately \$0.19 to produce a similar number of calories growing cattle for beef consumption. The same energy content of milk from cattle is also costly, at approximately \$0.16 per 1000 kcal. Much of this difference is due to the low NPE of cattle. Thus, there has been a growing movement worldwide to promote the consumption of non-meat and non-dairy foods so that less energy is wasted feeding animals for the meat industry.

## Modeling Ecosystems Energy Flow: Ecological Pyramids

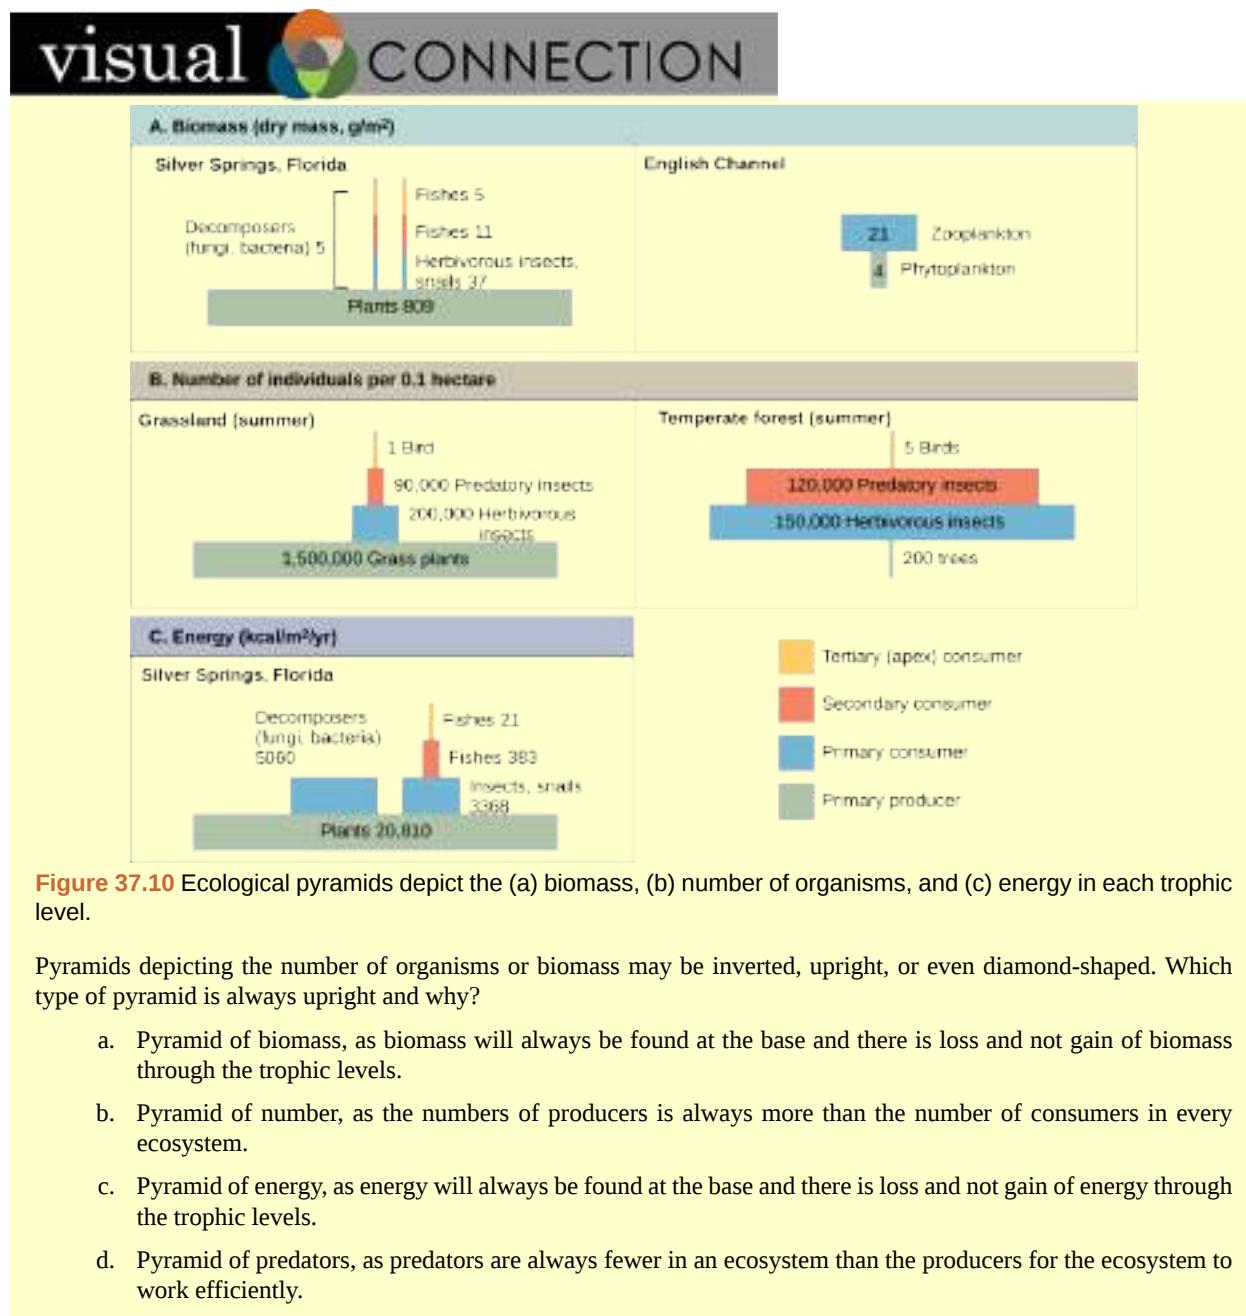

The structure of ecosystems can be visualized with ecological pyramids, which were first described by the pioneering studies of Charles Elton in the 1920s. **Ecological pyramids** show the relative amounts of various parameters (such as number of organisms, energy, and biomass) across trophic levels.

Pyramids of numbers can be either upright or inverted, depending on the ecosystem. As shown in **Figure 37.10**, typical grassland during the summer has a base of many plants and the numbers of organisms decrease at each trophic level. However, during the summer in a temperate forest, the base of the pyramid consists of few trees compared with the number of primary consumers, mostly insects. Because trees are large, they have great photosynthetic capability, and dominate other plants in this ecosystem to obtain sunlight. Even in smaller numbers, primary producers in forests are still capable of supporting other trophic levels.

Another way to visualize ecosystem structure is with pyramids of biomass. This pyramid measures the amount of energy converted into living tissue at the different trophic levels. Using the Silver Springs ecosystem example, this data exhibits an upright biomass pyramid (**Figure 37.10**), whereas the pyramid from the English Channel example is inverted. The plants (primary producers) of the Silver Springs ecosystem make up a large percentage of the biomass found there. However, the phytoplankton in the English Channel example make up less biomass than the primary consumers, the zooplankton. As with inverted pyramids of numbers, this inverted pyramid is not due to a lack of productivity from the primary producers, but results from the high turnover rate of the phytoplankton. The phytoplankton are consumed rapidly by the primary consumers, thus, minimizing their biomass at any particular point in time. However, phytoplankton reproduce quickly, thus they are able to support the rest of the ecosystem.

Pyramid ecosystem modeling can also be used to show energy flow through the trophic levels. Notice that these numbers

are the same as those used in the energy flow compartment diagram in **Figure 37.8**. Pyramids of energy are always upright, and an ecosystem without sufficient primary productivity cannot be supported. All types of ecological pyramids are useful for characterizing ecosystem structure. However, in the study of energy flow through the ecosystem, pyramids of energy are the most consistent and representative models of ecosystem structure (**Figure 37.10**).

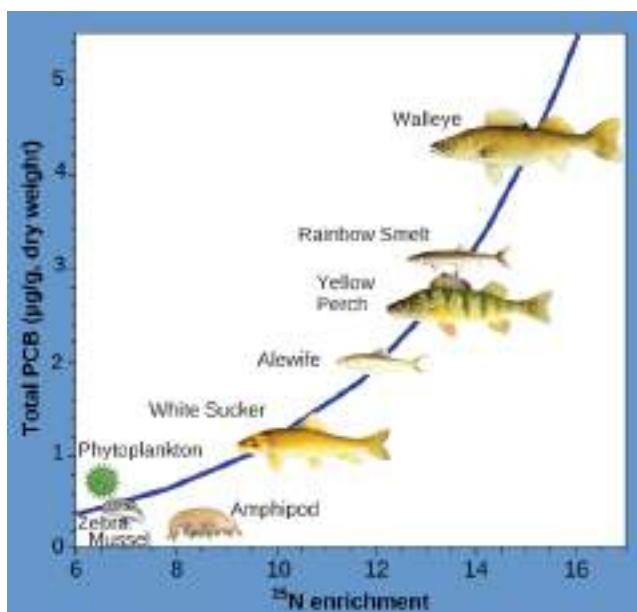

## Consequences of Food Webs: Biological Magnification

One of the most important environmental consequences of ecosystem dynamics is biomagnification. **Biomagnification** is the increasing concentration of persistent, toxic substances in organisms at each trophic level, from the primary producers to the apex consumers. Many substances have been shown to bioaccumulate, including classical studies with the pesticide dichlorodiphenyltrichloroethane (DDT), which was published in the 1960s bestseller, *Silent Spring*, by Rachel Carson. DDT was a commonly used pesticide before its dangers became known. In some aquatic ecosystems, organisms from each trophic level consumed many organisms of the lower level, which caused DDT to increase in birds (apex consumers) that

ate fish. Thus, the birds accumulated sufficient amounts of DDT to cause fragility in their eggshells. This effect increased egg breakage during nesting and was shown to have adverse effects on these bird populations. The use of DDT was banned in the United States in the 1970s.

Other substances that biomagnify are polychlorinated biphenyls (PCBs), which were used in coolant liquids in the United States until their use was banned in 1979, and heavy metals, such as mercury, lead, and cadmium. These substances were best studied in aquatic ecosystems, where fish species at different trophic levels accumulate toxic substances brought through the ecosystem by the primary producers. As illustrated in a study performed by the National Oceanic and Atmospheric Administration (NOAA) in the Saginaw Bay of Lake Huron (**Figure 37.11**), PCB concentrations increased from the ecosystem's primary producers (phytoplankton) through the different trophic levels of fish species. The apex consumer (walleye) has more than four times the amount of PCBs compared to phytoplankton. Also, based on results from other studies, birds that eat these fish may have PCB levels at least one order of magnitude higher than those found in the lake fish.

**Figure 37.11** This chart shows the PCB concentrations found at the various trophic levels in the Saginaw Bay ecosystem of Lake Huron. Numbers on the x-axis reflect enrichment with heavy isotopes of nitrogen ( $^{15}\text{N}$ ), which is a marker for increasing trophic level. Notice that the fish in the higher trophic levels accumulate more PCBs than those in lower trophic levels. (credit: Patricia Van Hoof, NOAA, GLERL)

Other concerns have been raised by the accumulation of heavy metals, such as mercury and cadmium, in certain types of seafood. The United States Environmental Protection Agency (EPA) recommends that pregnant women and young children should not consume any swordfish, shark, king mackerel, or tilefish because of their high mercury content. These individuals are advised to eat fish low in mercury: salmon, tilapia, shrimp, pollock, and catfish. Biomagnification is a good example of how ecosystem dynamics can affect our everyday lives, even influencing the food we eat.

## everyday CONNECTION for AP<sup>®</sup> Courses

Many people enjoy eating swordfish, but pregnant women and young children should avoid it due to its high mercury content resulting from biomagnification.

**Figure 37.12**

Why does biomagnification render larger, predatory species such as swordfish more toxic to humans than smaller, planktivorous species such as anchovies?

- a. Larger animals consume many small organisms, which leads to accumulation of oxygen in their body over time.
- b. Larger animals consume many small organisms, which leads to accumulation of mercury in their body over time.
- c. Larger animals consume many small organisms, which leads to accumulation of hydrogen in their body over time.
- d. Larger animals consume many small organisms, which leads to accumulation of polyglucose in their body over time.

## science practices CONNECTION for AP<sup>®</sup> Courses

### Lab Investigation

*AP<sup>®</sup> Biology Investigation Labs: Inquiry-Based Approach, Investigation 10: Energy Dynamics.* This inquiry-based investigation provides an opportunity for you to explore factors that govern energy capture, allocation, storage, and transfer between producers and consumers in a terrestrial ecosystem composed of Wisconsin Fast Plants (producers) and cabbage white butterfly (*Pieris rapae*) larvae.

### Activity

An ecosystem consists of earthworms, heterotrophic soil bacteria, grass, deer, beetles, and a lion. Create a mini-poster to describe the trophic structure of the ecosystem, how each organism receives inputs of energy and nutrients, where outputs (e.g., wastes) go, and the effect(s) each organisms has on the others. Include all energy transformations and transfers based on the hypothetical assumption that 9,500 J of net energy is available at the producer level.

## 37.3 | Biogeochemical Cycles

In this section, you will explore the following questions:

- What are the basic stages in the biogeochemical cycles of water, nitrogen, phosphorus, and sulfur?
- How have human activities impacted these biogeochemical cycles, and what are the potential consequences for Earth?

### Connection for AP® Courses

As we learned in **Energy Flow through Ecosystems**, energy takes a one-way path (flows directionally) through the trophic levels in an ecosystem. However, the matter that comprises living organisms is conserved and recycled through what are referred to as **biogeochemical cycles**. The six most common elements associated with organic molecules—carbon, nitrogen, hydrogen, oxygen, phosphorus, and sulfur—take a variety of chemical forms and may exist for long periods in Earth’s atmosphere, on land, in water, or beneath our planet’s surface. Geologic processes, including weathering and erosion, play a role in this recycling of materials from the environment to living organisms. For the purpose of AP®, you do *not* need to know the details of every biogeochemical cycle, though some details of those cycles are covered in this section.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 2 and Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Learning Objective</b>         | <b>2.9</b> The student is able to represent graphically or model quantitatively the exchange of molecules between an organism and its environment, and the subsequent use of these molecules to build new molecules that facilitate dynamic homeostasis, growth and reproduction. |
| <b>Big Idea 4</b>                 | Biological systems interact, and these systems and their interactions possess complex properties.                                                                                                                                                                                 |
| <b>Enduring Understanding 4.A</b> | Interactions within biological systems lead to complex properties.                                                                                                                                                                                                                |
| <b>Essential Knowledge</b>        | <b>4.A.6</b> Interactions among living systems and with their environment result in the movement of matter and energy.                                                                                                                                                            |
| <b>Science Practice</b>           | <b>1.4</b> The student can use representations and models to analyze situations or solve problems qualitatively and quantitatively.                                                                                                                                               |

|                           |                                                                                                                                                                                                                                                  |
|---------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Learning Objective</b> | <b>4.15</b> The student is able to use visual representations to analyze situations or solve problems qualitatively to illustrate how interactions among living systems and with their environment results in the movement of matter and energy. |
|---------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

Water contains hydrogen and oxygen, which is essential to all living processes. The **hydrosphere** is the area of the Earth where water movement and storage occurs: as liquid water on the surface and beneath the surface or frozen (rivers, lakes, oceans, groundwater, polar ice caps, and glaciers), and as water vapor in the atmosphere. Carbon is found in all organic macromolecules and is an important constituent of fossil fuels. Nitrogen is a major component of our nucleic acids and proteins and is critical to human agriculture. Phosphorus, a major component of nucleic acid (along with nitrogen), is one of the main ingredients in artificial fertilizers used in agriculture and their associated environmental impacts on our surface water. Sulfur, critical to the 3-D folding of proteins (as in disulfide binding), is released into the atmosphere by the burning of fossil fuels, such as coal.

The cycling of these elements is interconnected. For example, the movement of water is critical for the leaching of nitrogen and phosphate into rivers, lakes, and oceans. Furthermore, the ocean itself is a major reservoir for carbon. Thus, mineral nutrients are cycled, either rapidly or slowly, through the entire biosphere, from one living organism to another, and between the biotic and abiotic world.

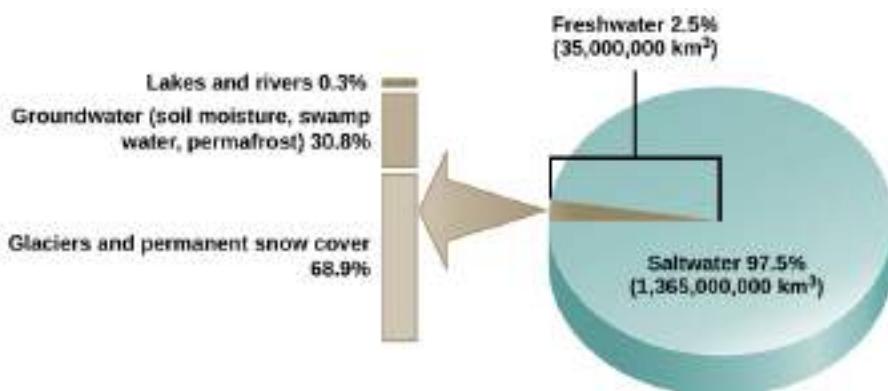

Head to this **website** (<http://openstaxcollege.org/l/biogeochemical>) to learn more about biogeochemical cycles.

What is true of geochemical cycles?

- a. There is a variable amount of each element on Earth.
- b. A reservoir is where elements remain through time.
- c. Only external energy sources drive movement of elements.
- d. Geochemical cycles are characterized by the movement of elements.

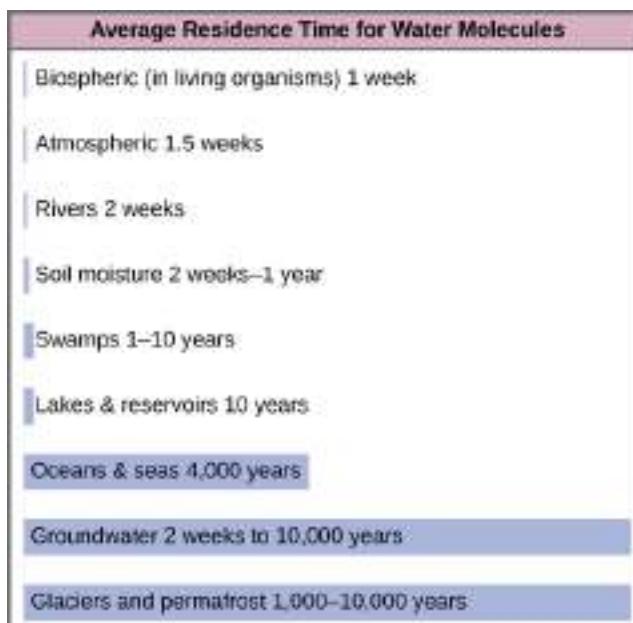

## The Water (Hydrologic) Cycle

Water is the basis of all living processes. The human body is more than 1/2 water and human cells are more than 70 percent water. Thus, most land animals need a supply of fresh water to survive. However, when examining the stores of water on Earth, 97.5 percent of it is non-potable salt water (Figure 37.13). Of the remaining water, 99 percent is locked underground as water or as ice. Thus, less than 1 percent of fresh water is easily accessible from lakes and rivers. Many living things, such as plants, animals, and fungi, are dependent on the small amount of fresh surface water supply, a lack of which can have massive effects on ecosystem dynamics. Humans, of course, have developed technologies to increase water availability, such as digging wells to harvest groundwater, storing rainwater, and using desalination to obtain drinkable water from the ocean. Although this pursuit of drinkable water has been ongoing throughout human history, the supply of fresh water is still a major issue in modern times.

**Figure 37.13** Only 2.5 percent of water on Earth is fresh water, and less than 1 percent of fresh water is easily accessible to living things.

Water cycling is extremely important to ecosystem dynamics. Water has a major influence on climate and, thus, on the environments of ecosystems, some located on distant parts of the Earth. Most of the water on Earth is stored for long periods in the oceans, underground, and as ice. **Figure 37.14** illustrates the average time that an individual water molecule may spend in the Earth's major water reservoirs. **Residence time** is a measure of the average time an individual water molecule stays in a particular reservoir. A large amount of the Earth's water is locked in place in these reservoirs as ice, beneath the ground, and in the ocean, and, thus, is unavailable for short-term cycling (only surface water can evaporate).

**Figure 37.14** This graph shows the average residence time for water molecules in the Earth's water reservoirs.

There are various processes that occur during the cycling of water, shown in **Figure 37.15**. These processes include the following:

- evaporation/sublimation
- condensation/precipitation
- subsurface water flow
- surface runoff/snowmelt
- streamflow

The water cycle is driven by the sun's energy as it warms the oceans and other surface waters. This leads to the evaporation (water to water vapor) of liquid surface water and the sublimation (ice to water vapor) of frozen water, which deposits large amounts of water vapor into the atmosphere. Over time, this water vapor condenses into clouds as liquid or frozen droplets and is eventually followed by precipitation (rain or snow), which returns water to the Earth's surface. Rain eventually

permeates into the ground, where it may evaporate again if it is near the surface, flow beneath the surface, or be stored for long periods. More easily observed is surface runoff: the flow of fresh water either from rain or melting ice. Runoff can then make its way through streams and lakes to the oceans or flow directly to the oceans themselves.

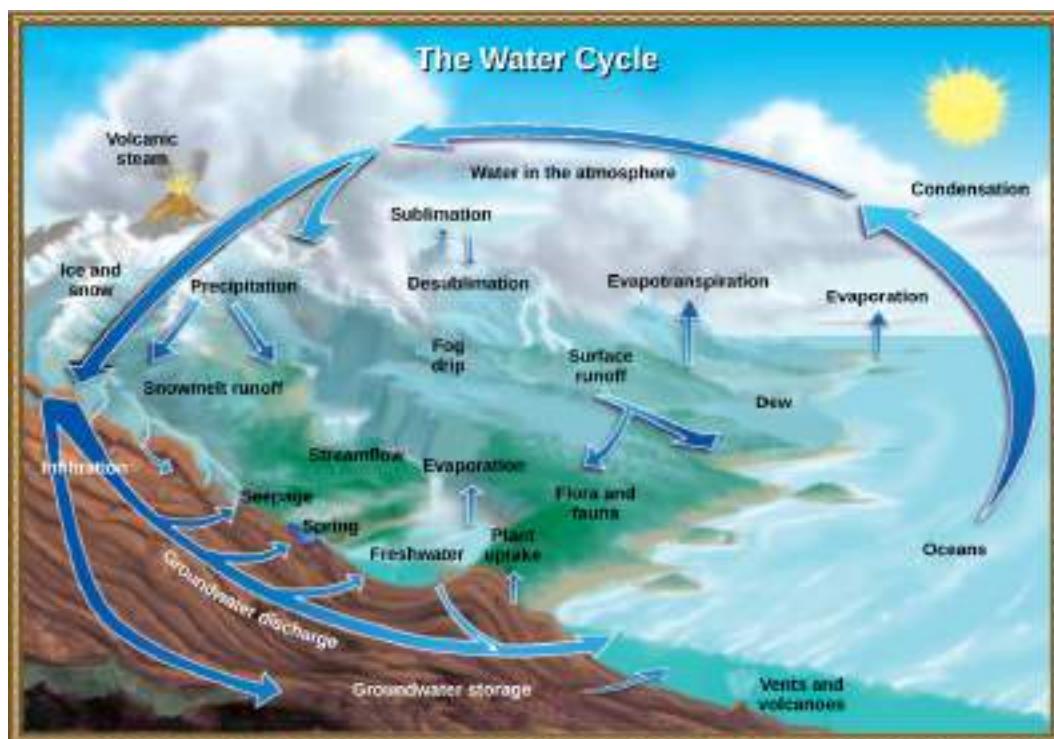

Head to this [website \(<http://openstaxcollege.org/l/freshwater>\)](http://openstaxcollege.org/l/freshwater) to learn more about the world's fresh water supply.

Water characterizes the most common and the most rare ecosystems worldwide. Why is it essential to find ways to manage water resources for human populations?

- Humans utilize water from oceans, which is the most common ecosystem.
- Humans utilize freshwater, which is the rarest ecosystem.
- Humans utilize freshwater, which is the most common ecosystem.
- Humans utilize water from oceans, which is the rarest ecosystem.

Rain and surface runoff are major ways in which minerals, including carbon, nitrogen, phosphorus, and sulfur, are cycled from land to water. The environmental effects of runoff will be discussed later as these cycles are described.

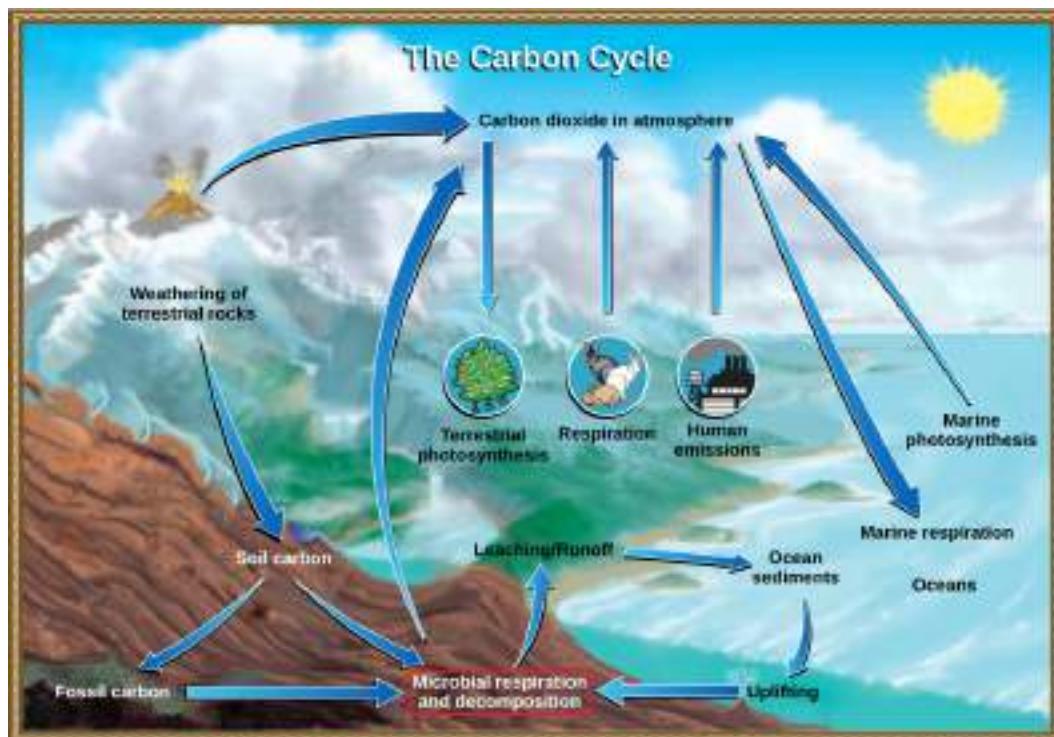

**Figure 37.15** Water from the land and oceans enters the atmosphere by evaporation or sublimation, where it condenses into clouds and falls as rain or snow. Precipitated water may enter freshwater bodies or infiltrate the soil. The cycle is complete when surface or groundwater reenters the ocean. (credit: modification of work by John M. Evans and Howard Perlman, USGS)

## The Carbon Cycle

Carbon is the second most abundant element in living organisms. Carbon is present in all organic molecules, and its role in the structure of macromolecules is of primary importance to living organisms. Carbon compounds contain especially high energy, particularly those derived from fossilized organisms, mainly plants, which humans use as fuel. Since the 1800s, the number of countries using massive amounts of fossil fuels has increased. Since the beginning of the Industrial Revolution, global demand for the Earth's limited fossil fuel supplies has risen; therefore, the amount of carbon dioxide in our atmosphere has increased. This increase in carbon dioxide has been associated with climate change and other disturbances of the Earth's ecosystems and is a major environmental concern worldwide. Thus, the "carbon footprint" is based on how much carbon dioxide is produced and how much fossil fuel countries consume.

The carbon cycle is most easily studied as two interconnected sub-cycles: one dealing with rapid carbon exchange among living organisms and the other dealing with the long-term cycling of carbon through geologic processes. The entire carbon cycle is shown in **Figure 37.16**.

**Figure 37.16** Carbon dioxide gas exists in the atmosphere and is dissolved in water. Photosynthesis converts carbon dioxide gas to organic carbon, and respiration cycles the organic carbon back into carbon dioxide gas. Long-term storage of organic carbon occurs when matter from living organisms is buried deep underground and becomes fossilized. Volcanic activity and, more recently, human emissions, bring this stored carbon back into the carbon cycle. (credit: modification of work by John M. Evans and Howard Perlman, USGS)

Click this **link** (<http://openstaxcollege.org/l/themecarbon>) to read information about the United States Carbon Cycle Science Program.

Compare and contrast carbon sources and sinks, and provide one example of each.

- a. Carbon sources, such as burning fossil fuels, produce carbon while carbon sinks, such as oceans, absorb carbon.
- b. Carbon sources, such as volcanic activity, absorb carbon while carbon sinks, such as vegetation, produce carbon.
- c. Carbon sources, such as vegetation, produce carbon while carbon sinks, such as volcanic activity, absorb carbon.
- d. Carbon sources, such as volcanic activity, produce carbon while carbon sinks, such as burning fossil fuels, absorb carbon.

### ***The Biological Carbon Cycle***

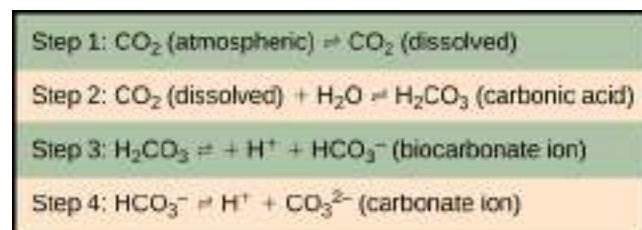

Living organisms are connected in many ways, even between ecosystems. A good example of this connection is the exchange of carbon between autotrophs and heterotrophs within and between ecosystems by way of atmospheric carbon dioxide. Carbon dioxide is the basic building block that most autotrophs use to build multi-carbon, high energy compounds, such as glucose. The energy harnessed from the sun is used by these organisms to form the covalent bonds that link carbon atoms together. These chemical bonds thereby store this energy for later use in the process of respiration. Most terrestrial autotrophs obtain their carbon dioxide directly from the atmosphere, while marine autotrophs acquire it in the dissolved form (carbonic acid,  $\text{H}_2\text{CO}_3^-$ ). However carbon dioxide is acquired, a by-product of the process is oxygen. The photosynthetic organisms are responsible for depositing approximately 21 percent oxygen content of the atmosphere that we observe today.

Heterotrophs and autotrophs are partners in biological carbon exchange (especially the primary consumers, largely herbivores). Heterotrophs acquire the high-energy carbon compounds from the autotrophs by consuming them, and breaking them down by respiration to obtain cellular energy, such as ATP. The most efficient type of respiration, aerobic respiration, requires oxygen obtained from the atmosphere or dissolved in water. Thus, there is a constant exchange of oxygen and carbon dioxide between the autotrophs (which need the carbon) and the heterotrophs (which need the oxygen). Gas exchange through the atmosphere and water is one way that the carbon cycle connects all living organisms on Earth.

### ***The Biogeochemical Carbon Cycle***

The movement of carbon through the land, water, and air is complex, and in many cases, it occurs much more slowly geologically than as seen between living organisms. Carbon is stored for long periods in what are known as carbon reservoirs, which include the atmosphere, bodies of liquid water (mostly oceans), ocean sediment, soil, land sediments (including fossil fuels), and the Earth's interior.

As stated, the atmosphere is a major reservoir of carbon in the form of carbon dioxide and is essential to the process of photosynthesis. The level of carbon dioxide in the atmosphere is greatly influenced by the reservoir of carbon in the oceans. The exchange of carbon between the atmosphere and water reservoirs influences how much carbon is found in each location, and each one affects the other reciprocally. Carbon dioxide ( $\text{CO}_2$ ) from the atmosphere dissolves in water and combines with water molecules to form carbonic acid, and then it ionizes to carbonate and bicarbonate ions ([Figure 37.17](#))

**Figure 37.17** Carbon dioxide reacts with water to form bicarbonate and carbonate ions.

The equilibrium coefficients are such that more than 90 percent of the carbon in the ocean is found as bicarbonate ions. Some of these ions combine with seawater calcium to form calcium carbonate ( $\text{CaCO}_3$ ), a major component of marine organism shells. These organisms eventually form sediments on the ocean floor. Over geologic time, the calcium carbonate forms limestone, which comprises the largest carbon reservoir on Earth.

On land, carbon is stored in soil as a result of the decomposition of living organisms (by decomposers) or from weathering of terrestrial rock and minerals. This carbon can be leached into the water reservoirs by surface runoff. Deeper underground, on land and at sea, are fossil fuels: the anaerobically decomposed remains of plants that take millions of years to form. Fossil fuels are considered a non-renewable resource because their use far exceeds their rate of formation. A **non-renewable resource**, such as fossil fuel, is either regenerated very slowly or not at all. Another way for carbon to enter the atmosphere is from land (including land beneath the surface of the ocean) by the eruption of volcanoes and other geothermal systems. Carbon sediments from the ocean floor are taken deep within the Earth by the process of **subduction**: the movement of one tectonic plate beneath another. Carbon is released as carbon dioxide when a volcano erupts or from volcanic hydrothermal vents.

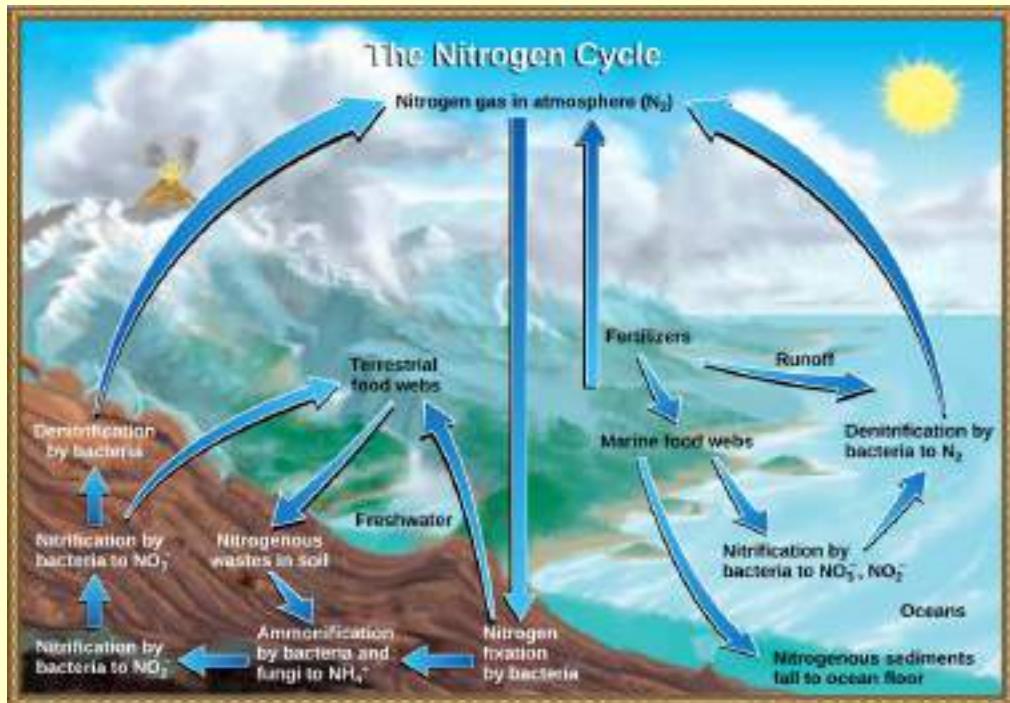

Carbon dioxide is also added to the atmosphere by the animal husbandry practices of humans. The large numbers of land animals raised to feed the Earth's growing population results in increased carbon dioxide levels in the atmosphere due to farming practices and the respiration and methane production. This is another example of how human activity indirectly affects biogeochemical cycles in a significant way. Although much of the debate about the future effects of increasing atmospheric carbon on climate change focuses on fossils fuels, scientists take natural processes, such as volcanoes and respiration, into account as they model and predict the future impact of this increase.

## The Nitrogen Cycle

Getting nitrogen into the living world is difficult. Plants and phytoplankton are not equipped to incorporate nitrogen from the atmosphere (which exists as tightly bonded, triple covalent  $\text{N}_2$ ) even though this molecule comprises approximately 78 percent of the atmosphere. Nitrogen enters the living world via free-living and symbiotic bacteria, which incorporate nitrogen into their macromolecules through nitrogen fixation (conversion of  $\text{N}_2$ ). Cyanobacteria live in most aquatic ecosystems where sunlight is present; they play a key role in nitrogen fixation. Cyanobacteria are able to use inorganic sources of nitrogen to "fix" nitrogen. *Rhizobium* bacteria live symbiotically in the root nodules of legumes (such as peas, beans, and peanuts) and provide them with the organic nitrogen they need. Free-living bacteria, such as *Azotobacter*, are also important nitrogen fixers.

Organic nitrogen is especially important to the study of ecosystem dynamics since many ecosystem processes, such as primary production and decomposition, are limited by the available supply of nitrogen. As shown in **Figure 37.18**, the nitrogen that enters living systems by nitrogen fixation is successively converted from organic nitrogen back into nitrogen gas by bacteria. This process occurs in three steps in terrestrial systems: ammonification, nitrification, and denitrification. First, the ammonification process converts nitrogenous waste from living animals or from the remains of dead animals into ammonium ( $\text{NH}_4^+$ ) by certain bacteria and fungi. Second, the ammonium is converted to nitrites ( $\text{NO}_2^-$ ) by nitrifying bacteria, such as *Nitrosomonas*, through nitrification. Subsequently, nitrites are converted to nitrates ( $\text{NO}_3^-$ ) by similar organisms. Third, the process of denitrification occurs, whereby bacteria, such as *Pseudomonas* and *Clostridium*, convert the nitrates into nitrogen gas, allowing it to re-enter the atmosphere.

## visual CONNECTION

**Figure 37.18** Nitrogen enters the living world from the atmosphere via nitrogen-fixing bacteria. This nitrogen and nitrogenous waste from animals is then processed back into gaseous nitrogen by soil bacteria, which also supply terrestrial food webs with the organic nitrogen they need. (credit: modification of work by John M. Evans and Howard Perlman, USGS)

Which of the following statements about the nitrogen cycle is false?

- Ammonification converts organic nitrogenous matter from living organisms into ammonium ( $\text{NH}_4^+$ ).
- Denitrification by bacteria converts nitrates ( $\text{NO}_3^-$ ) to nitrogen gas ( $\text{N}_2$ ).
- Nitrification by bacteria converts nitrates ( $\text{NO}_3^-$ ) to nitrites ( $\text{NO}_2^-$ ).
- Nitrogen fixing bacteria convert nitrogen gas ( $\text{N}_2$ ) into organic compounds.

Human activity can release nitrogen into the environment by two primary means: the combustion of fossil fuels, which releases different nitrogen oxides, and by the use of artificial fertilizers in agriculture, which are then washed into lakes, streams, and rivers by surface runoff. Atmospheric nitrogen is associated with several effects on Earth's ecosystems including the production of acid rain (as nitric acid,  $\text{HNO}_3$ ) and greenhouse gas (as nitrous oxide,  $\text{N}_2\text{O}$ ) potentially causing climate change. A major effect from fertilizer runoff is saltwater and freshwater **eutrophication**, a process whereby nutrient runoff causes the excess growth of microorganisms, depleting dissolved oxygen levels and killing ecosystem fauna.

A similar process occurs in the marine nitrogen cycle, where the ammonification, nitrification, and denitrification processes are performed by marine bacteria. Some of this nitrogen falls to the ocean floor as sediment, which can then be moved to land in geologic time by uplift of the Earth's surface and thereby incorporated into terrestrial rock. Although the movement of nitrogen from rock directly into living systems has been traditionally seen as insignificant compared with nitrogen fixed from the atmosphere, a recent study showed that this process may indeed be significant and should be included in any study of the global nitrogen cycle.<sup>[3]</sup>

## science practices CONNECTION for AP<sup>®</sup> Courses

### Think About It

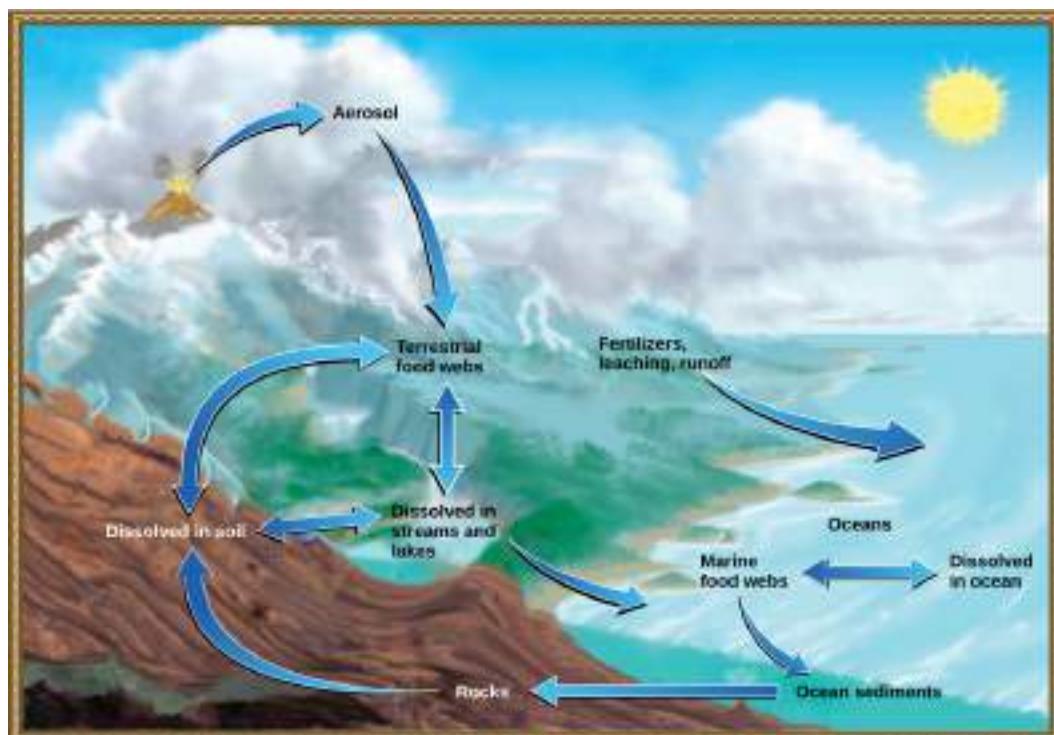

What is the process of nitrogen fixation and how does it relate to crop rotation in agriculture?

## The Phosphorus Cycle

Phosphorus is an essential nutrient for living processes; it is a major component of nucleic acid and phospholipids, and, as calcium phosphate, makes up the supportive components of our bones. Phosphorus is often the limiting nutrient (necessary for growth) in aquatic ecosystems (Figure 37.19).

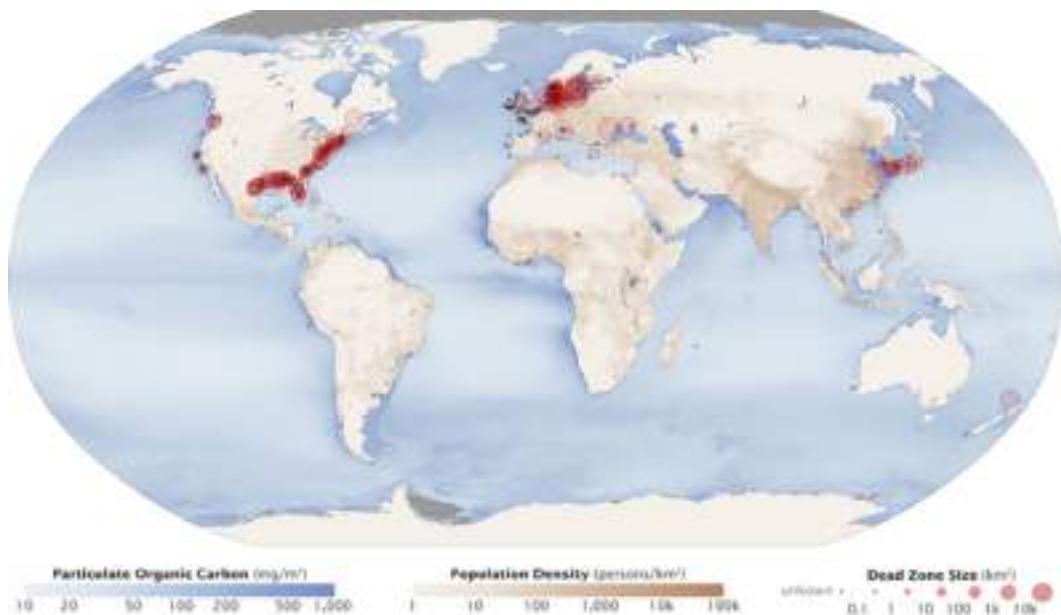

Phosphorus occurs in nature as the phosphate ion ( $\text{PO}_4^{3-}$ ). In addition to phosphate runoff as a result of human activity, natural surface runoff occurs when it is leached from phosphate-containing rock by weathering, thus sending phosphates into rivers, lakes, and the ocean. This rock has its origins in the ocean. Phosphate-containing ocean sediments form primarily from the bodies of ocean organisms and from their excretions. However, in remote regions, volcanic ash, aerosols, and mineral dust may also be significant phosphate sources. This sediment then is moved to land over geologic time by the uplifting of areas of the Earth's surface.

Phosphorus is also reciprocally exchanged between phosphate dissolved in the ocean and marine ecosystems. The movement of phosphate from the ocean to the land and through the soil is extremely slow, with the average phosphate ion having an oceanic residence time between 20,000 and 100,000 years.

**Figure 37.19** In nature, phosphorus exists as the phosphate ion ( $\text{PO}_4^{3-}$ ). Weathering of rocks and volcanic activity releases phosphate into the soil, water, and air, where it becomes available to terrestrial food webs. Phosphate enters the oceans via surface runoff, groundwater flow, and river flow. Phosphate dissolved in ocean water cycles into marine food webs. Some phosphate from the marine food webs falls to the ocean floor, where it forms sediment. (credit: modification of work by John M. Evans and Howard Perlman, USGS)

Excess phosphorus and nitrogen that enters these ecosystems from fertilizer runoff and from sewage causes excessive growth of microorganisms and depletes the dissolved oxygen, which leads to the death of many ecosystem fauna, such as shellfish and finfish. This process is responsible for dead zones in lakes and at the mouths of many major rivers (Figure 37.19).

**Figure 37.20** Dead zones occur when phosphorus and nitrogen from fertilizers cause excessive growth of microorganisms, which depletes oxygen and kills fauna. Worldwide, large dead zones are found in coastal areas of high population density. (credit: NASA Earth Observatory)

A **dead zone** is an area within a freshwater or marine ecosystem where large areas are depleted of their normal flora and fauna; these zones can be caused by eutrophication, oil spills, dumping of toxic chemicals, and other human activities. The number of dead zones has been increasing for several years, and more than 400 of these zones were present as of 2008. One of the worst dead zones is off the coast of the United States in the Gulf of Mexico, where fertilizer runoff from the Mississippi River basin has created a dead zone of over 8463 square miles. Phosphate and nitrate runoff from fertilizers also negatively affect several lake and bay ecosystems including the Chesapeake Bay in the eastern United States.

## everyday CONNECTION

### Chesapeake Bay

**Figure 37.21** This (a) satellite image shows the Chesapeake Bay, an ecosystem affected by phosphate and nitrate runoff. A (b) member of the Army Corps of Engineers holds a clump of oysters being used as a part of the oyster restoration effort in the bay. (credit a: modification of work by NASA/MODIS; credit b: modification of work by U.S. Army)

The Chesapeake Bay has long been valued as one of the most scenic areas on Earth; it is now in distress and is recognized as a declining ecosystem. In the 1970s, the Chesapeake Bay was one of the first ecosystems to have identified dead zones, which continue to kill many fish and bottom-dwelling species, such as clams, oysters, and worms. Several species have declined in the Chesapeake Bay due to surface water runoff containing excess nutrients from artificial fertilizer used on land. The source of the fertilizers (with high nitrogen and phosphate content) is not limited to agricultural practices. There are many nearby urban areas and more than 150 rivers and streams empty into the bay that are carrying fertilizer runoff from lawns and gardens. Thus, the decline of the Chesapeake Bay is a complex issue and requires the cooperation of industry, agriculture, and everyday homeowners.

Of particular interest to conservationists is the oyster population; it is estimated that more than 200,000 acres of oyster reefs existed in the bay in the 1700s, but that number has now declined to only 36,000 acres. Oyster harvesting was once a major industry for Chesapeake Bay, but it declined 88 percent between 1982 and 2007. This decline was due not only to fertilizer runoff and dead zones but also to overharvesting. Oysters require a certain minimum population density because they must be in close proximity to reproduce. Human activity has altered the oyster population and locations, greatly disrupting the ecosystem.

The restoration of the oyster population in the Chesapeake Bay has been ongoing for several years with mixed success. Not only do many people find oysters good to eat, but they also clean up the bay. Oysters are filter feeders, and as they eat, they clean the water around them. In the 1700s, it was estimated that it took only a few days for the oyster population to filter the entire volume of the bay. Today, with changed water conditions, it is estimated that the present population would take nearly a year to do the same job.

Restoration efforts have been ongoing for several years by non-profit organizations, such as the Chesapeake Bay Foundation. The restoration goal is to find a way to increase population density so the oysters can reproduce more efficiently. Many disease-resistant varieties (developed at the Virginia Institute of Marine Science for the College of William and Mary) are now available and have been used in the construction of experimental oyster reefs. Efforts to clean and restore the bay by Virginia and Delaware have been hampered because much of the pollution entering the bay comes from other states, which stresses the need for inter-state cooperation to gain successful restoration.

The new, hearty oyster strains have also spawned a new and economically viable industry—oyster

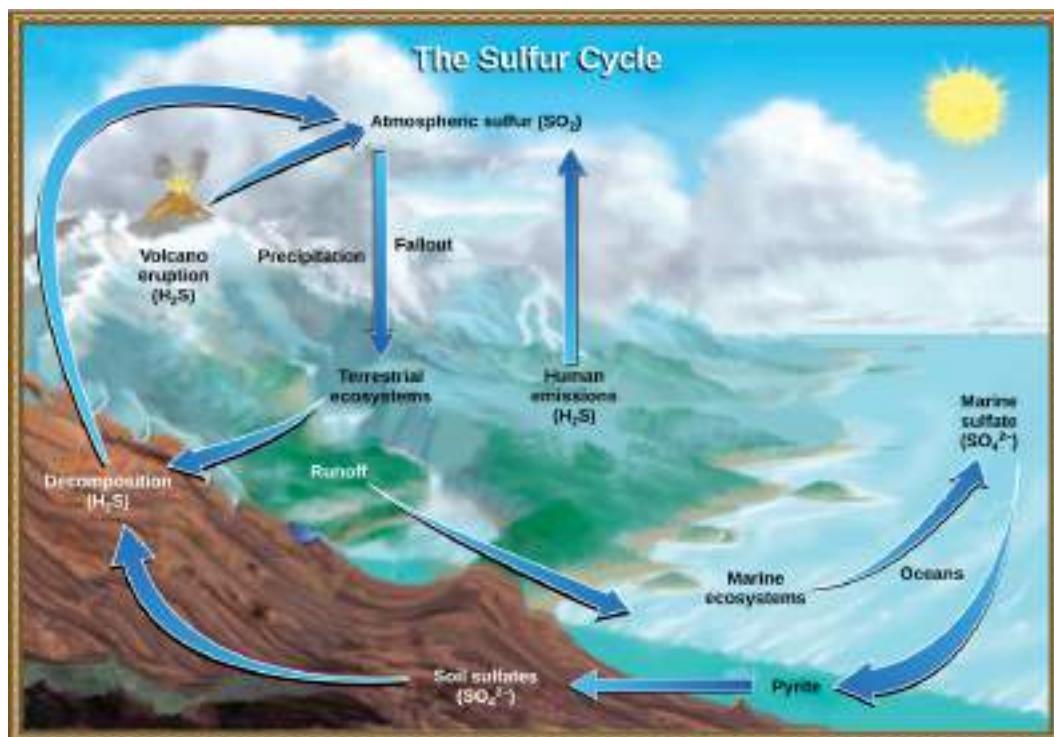

aquaculture—which not only supplies oysters for food and profit, but also has the added benefit of cleaning the bay.

How did fertilizer runoff produce a dead zone in the Chesapeake Bay?

- Excess nitrogen from fertilizer decreases microbial growth, depleting dissolved oxygen in water, thereby killing the fauna of the ecosystem.
- Fertilizer runoff decreases the carbon dioxide concentration in water, thereby killing fauna of the ecosystem.
- Fertilizer runoff produces a dead zone in the Chesapeake Bay by increasing oxygen concentration in the ecosystem.
- Excess nitrogen from fertilizer increases microbial growth, depleting dissolved oxygen in water, thereby killing the fauna of the ecosystem.

## The Sulfur Cycle

Sulfur is an essential element for the macromolecules of living things. As a part of the amino acid cysteine, it is involved in the formation of disulfide bonds within proteins, which help to determine their 3-D folding patterns, and hence their functions. As shown in **Figure 37.21**, sulfur cycles between the oceans, land, and atmosphere. Atmospheric sulfur is found in the form of sulfur dioxide ( $\text{SO}_2$ ) and enters the atmosphere in three ways: from the decomposition of organic molecules, from volcanic activity and geothermal vents, and from the burning of fossil fuels by humans.

**Figure 37.22** Sulfur dioxide from the atmosphere becomes available to terrestrial and marine ecosystems when it is dissolved in precipitation as weak sulfuric acid or when it falls directly to the Earth as fallout. Weathering of rocks also makes sulfates available to terrestrial ecosystems. Decomposition of living organisms returns sulfates to the ocean, soil and atmosphere. (credit: modification of work by John M. Evans and Howard Perlman, USGS)

On land, sulfur is deposited in four major ways: precipitation, direct fallout from the atmosphere, rock weathering, and geothermal vents (**Figure 37.22**). Atmospheric sulfur is found in the form of sulfur dioxide ( $\text{SO}_2$ ), and as rain falls through the atmosphere, sulfur is dissolved in the form of weak sulfuric acid ( $\text{H}_2\text{SO}_4$ ). Sulfur can also fall directly from the atmosphere in a process called **fallout**. Also, the weathering of sulfur-containing rocks releases sulfur into the soil. These rocks originate from ocean sediments that are moved to land by the geologic uplifting of ocean sediments. Terrestrial ecosystems can then make use of these soil sulfates ( $\text{SO}_4^{2-}$ ), and upon the death and decomposition of these organisms, release the sulfur back into the atmosphere as hydrogen sulfide ( $\text{H}_2\text{S}$ ) gas.

**Figure 37.23** At this sulfur vent in Lassen Volcanic National Park in northeastern California, the yellowish sulfur deposits are visible near the mouth of the vent.

Sulfur enters the ocean via runoff from land, from atmospheric fallout, and from underwater geothermal vents. Some ecosystems (Figure 37.9) rely on chemoautotrophs using sulfur as a biological energy source. This sulfur then supports marine ecosystems in the form of sulfates.

Human activities have played a major role in altering the balance of the global sulfur cycle. The burning of large quantities of fossil fuels, especially from coal, releases larger amounts of hydrogen sulfide gas into the atmosphere. As rain falls through this gas, it creates the phenomenon known as acid rain. **Acid rain** is corrosive rain caused by rainwater falling to the ground through sulfur dioxide gas, turning it into weak sulfuric acid, which causes damage to aquatic ecosystems. Acid rain damages the natural environment by lowering the pH of lakes, which kills many of the resident fauna; it also affects the man-made environment through the chemical degradation of buildings. For example, many marble monuments, such as the Lincoln Memorial in Washington, DC, have suffered significant damage from acid rain over the years. These examples show the wide-ranging effects of human activities on our environment and the challenges that remain for our future.

Click this **link** ([http://openstaxcollege.org/l/climate\\_change](http://openstaxcollege.org/l/climate_change)) to learn more about global climate change.

The greenhouse effect is considered natural and essential to human survival. Why, then, is society concerned about the impact of human activities on the greenhouse gas effect?

- a. The greenhouse effect is reduced due to human activities.
- b. Human activities strengthen the greenhouse effect by trapping more heat in the atmosphere.
- c. Human activities decrease the release of carbon dioxide gas, thereby strengthening the greenhouse effect.
- d. Human activities cause less heat to be trapped in the atmosphere and decrease the temperature.

## KEY TERMS

**acid rain** corrosive rain caused by rainwater falling to the ground through sulfur dioxide gas, turning it into weak sulfuric acid; can damage structures and ecosystems

**analytical model** ecosystem model that is created with mathematical formulas to predict the effects of environmental disturbances on ecosystem structure and dynamics

**apex consumer** organism at the top of the food chain

**assimilation** biomass consumed and assimilated from the previous trophic level after accounting for the energy lost due to incomplete ingestion of food, energy used for respiration, and energy lost as waste

**biogeochemical cycle** cycling of mineral nutrients through ecosystems and through the non-living world

**biomagnification** increasing concentrations of persistent, toxic substances in organisms at each trophic level, from the primary producers to the apex consumers

**biomass** total weight, at the time of measurement, of living or previously living organisms in a unit area within a trophic level

**chemoautotroph** organism capable of synthesizing its own food using energy from inorganic molecules

**conceptual model** (also, compartment models) ecosystem model that consists of flow charts that show the interactions of different compartments of the living and non-living components of the ecosystem

**dead zone** area within an ecosystem in lakes and near the mouths of rivers where large areas of ecosystems are depleted of their normal flora and fauna; these zones can be caused by eutrophication, oil spills, dumping of toxic chemicals, and other human activities

**detrital food web** type of food web in which the primary consumers consist of decomposers; these are often associated with grazing food webs within the same ecosystem

**ecological pyramid** (also, Eltonian pyramid) graphical representation of different trophic levels in an ecosystem based of organism numbers, biomass, or energy content

**ecosystem** community of living organisms and their interactions with their abiotic environment

**ecosystem dynamics** study of the changes in ecosystem structure caused by changes in the environment or internal forces

**equilibrium** steady state of an ecosystem where all organisms are in balance with their environment and each other

**eutrophication** process whereby nutrient runoff causes the excess growth of microorganisms, depleting dissolved oxygen levels and killing ecosystem fauna

**fallout** direct deposit of solid minerals on land or in the ocean from the atmosphere

**food chain** linear representation of a chain of primary producers, primary consumers, and higher-level consumers used to describe ecosystem structure and dynamics

**food web** graphic representation of a holistic, non-linear web of primary producers, primary consumers, and higher-level consumers used to describe ecosystem structure and dynamics

**grazing food web** type of food web in which the primary producers are either plants on land or phytoplankton in the water; often associated with a detrital food web within the same ecosystem

**gross primary productivity** rate at which photosynthetic primary producers incorporate energy from the sun

**holistic ecosystem model** study that attempts to quantify the composition, interactions, and dynamics of entire ecosystems; often limited by economic and logistical difficulties, depending on the ecosystem

**hydrosphere** area of the Earth where water movement and storage occurs

**mesocosm** portion of a natural ecosystem to be used for experiments

**microcosm** re-creation of natural ecosystems entirely in a laboratory environment to be used for experiments

**net consumer productivity** energy content available to the organisms of the next trophic level

**net primary productivity** energy that remains in the primary producers after accounting for the organisms' respiration and heat loss

**net production efficiency (NPE)** measure of the ability of a trophic level to convert the energy it receives from the previous trophic level into biomass

**non-renewable resource** resource, such as fossil fuel, that is either regenerated very slowly or not at all

**primary consumer** trophic level that obtains its energy from the primary producers of an ecosystem

**primary producer** trophic level that obtains its energy from sunlight, inorganic chemicals, or dead and/or decaying organic material

**residence time** measure of the average time an individual water molecule stays in a particular reservoir

**resilience (ecological)** speed at which an ecosystem recovers equilibrium after being disturbed

**resistance (ecological)** ability of an ecosystem to remain at equilibrium in spite of disturbances

**secondary consumer** usually a carnivore that eat primary consumers

**simulation model** ecosystem model that is created with computer programs to holistically model ecosystems and to predict the effects of environmental disturbances on ecosystem structure and dynamics

**subduction** movement of one tectonic plate beneath another

**tertiary consumer** carnivore that eat other carnivores

**trophic level** position of a species or group of species in a food chain or a food web

**trophic level transfer efficiency (TLTE)** energy transfer efficiency between two successive trophic levels

## CHAPTER SUMMARY

### 37.1 Ecology for Ecosystems

Ecosystems exist on land, at sea, in the air, and underground. Different ways of modeling ecosystems are necessary to understand how environmental disturbances will affect ecosystem structure and dynamics. Conceptual models are useful to show the general relationships between organisms and the flow of materials or energy between them. Analytical models are used to describe linear food chains, and simulation models work best with holistic food webs.

### 37.2 Energy Flow through Ecosystems

Organisms in an ecosystem acquire energy in a variety of ways, which is transferred between trophic levels as the energy flows from the bottom to the top of the food web, with energy being lost at each transfer. The efficiency of these transfers is important for understanding the different behaviors and eating habits of warm-blooded versus cold-blooded animals. Modeling of ecosystem energy is best done with ecological pyramids of energy, although other ecological pyramids provide other vital information about ecosystem structure.

### 37.3 Biogeochemical Cycles

Mineral nutrients are cycled through ecosystems and their environment. Of particular importance are water, carbon, nitrogen, phosphorus, and sulfur. All of these cycles have major impacts on ecosystem structure and function. As human activities have caused major disturbances to these cycles, their study and modeling is especially important. A variety of

human activities, such as pollution, oil spills, and events) have damaged ecosystems, potentially causing global climate change. The health of Earth depends on understanding these cycles and how to protect the environment from irreversible damage.

## REVIEW QUESTIONS

1. What type of ecosystem is the rarest on Earth, among both terrestrial and aquatic ecosystems?
  - a. ocean
  - b. freshwater
  - c. grasslands
  - d. tundra
2. If an ecosystem is considered to be highly resilient, what can be inferred about that ecosystem?
  - a. The ecosystem is in a steady state.
  - b. The ecosystem has the ability to remain in equilibrium despite disturbance.
  - c. The ecosystem recovers quickly from disturbance.
  - d. The ecosystem is exposed to disturbances.
3. What is a re-created ecosystem in a laboratory environment known as?
  - a. mesocosm
  - b. simulation
  - c. microcosm
  - d. duplication
4. A scientist wants to analyze how deer grazing alters plant species composition in a forest and sections off a portion of the forest for observation and analysis. What type of system is the scientist using?
  - a. mesocosm
  - b. simulation
  - c. microcosm
  - d. duplication
5. What term describes the use of mathematical equations in the modeling of linear aspects of ecosystems?
  - a. analytical modeling
  - b. simulation modeling
  - c. conceptual modeling
  - d. microcosm modeling
6. If a scientist constructs a flow chart to depict the interactions among species in an estuary, what kind of model is she creating?
  - a. analytical model
  - b. stimulation model
  - c. conceptual model
  - d. microcosm model
7. What are usually the primary producers in an ocean grazing food web?
  - a. plants
  - b. animals
  - c. fungi
  - d. phytoplankton
8. Which of the following statements is true of trophic levels in an ecosystem?
  - a. Food chains are accurate representations of dynamics in an ecosystem.
  - b. In terrestrial ecosystems, primary producers commonly eat plants.
  - c. Food webs are easier to interpret than food chains.
  - d. The least amount of energy is available at the top of a food chain.
9. Where are coral reefs found?
  - a. shallow ocean water
  - b. deep ocean water
  - c. deep ocean surfaces
  - d. shallow freshwater
10. What is the weight of living organisms in an ecosystem at a particular point in time known as?
  - a. energy
  - b. productivity
  - c. entropy
  - d. biomass
11. If you wanted to measure gross primary productivity in a terrestrial ecosystem, what would you measure?
  - a. rate of energy incorporation by plants
  - b. energy available after a plant incorporates energy for its own biological functions
  - c. amount of energy from plants entering the trophic level of deer
  - d. total mass of plants and animals in an area at a given point in time

- 12.** What law of chemistry determines how much energy can be transferred when it is converted from one form to another?
- the first law of thermodynamics
  - the second law of thermodynamics
  - the conservation of matter
  - the conservation of energy
- 13.** What is the primary factor that limits the length of food chains in ecosystems?
- low energy transfer efficiency between trophic levels
  - too much net primary productivity
  - excess assimilation
  - low gross primary productivity
- 14.** What type of pyramid is considered the most representative of ecosystem structure?
- biomass
  - energy
  - number of organisms
  - number of species
- 15.** Why are the numbers of primary producers smaller than the number of primary consumers in the English Channel ecosystem?
- The primary consumers have a high turnover rate.
  - The primary producers have a low turnover rate.
  - The apex consumers have a low turnover rate.
  - The primary producers have a high turnover rate.
- 16.** What forms of life are found in areas where sunlight is unavailable and use inorganic molecules as an energy source?
- photoautotrophs
  - chemoautotrophs
  - primary consumers
  - secondary consumers
- 17.** What is the process whereby nitrogen is brought into organic molecules called?
- a.** nitrification  
**b.** denitrification  
**c.** nitrogen fixation  
**d.** nitrogen cycling
- 18.** Which of the following is a mechanism by which phosphorus is released into the environment?
- rock weathering
  - decomposition of organic molecules
  - volcanic activity
  - geothermal vent activity
- 19.** What is produced by eutrophication via excess nitrogen where a hydrologic reservoir lacks normal flora and fauna?
- fixation
  - acid rain
  - dead zones
  - nitrification
- 20.** What is a potential consequence of excess phosphorus and nitrogen in an ecosystem?
- This could result in increased global temperatures.
  - Subduction can be promoted.
  - These elements might be fixed in excess.
  - A dead zone could be produced from depleted oxygen.
- 21.** What term is given for freshwater that flows from rain or melting ice in the hydrologic cycle?
- residence time
  - surface runoff
  - evaporation
  - sublimation
- 22.** What most strongly influences how much carbon is present in a given location?
- number of bacteria
  - runoff
  - eutrophication
  - atmosphere and water exchange

## CRITICAL THINKING QUESTIONS

- 23.** Why does grouping terrestrial organisms into biomes obscure diversity?

- a. Biomes groups terrestrial organisms only on the basis of similar habitat conditions.
- b. Organisms belonging to a similar biome have dissimilarities in their makeup.
- c. There is variation within different types of biomes that biome categorization does not capture.
- d. Terrestrial biomes are defined based only on the growth form of the dominant vegetation.

**24.** Why are mesocosm and microcosm experiments not considered to represent the true nature of ecosystems?

- a. The ecosystem is either recreated or partitioned in both the experiments, which may alter the dynamics of the ecosystem the experiments are aiming to analyze.
- b. In both the experiments, dynamics of the ecosystem may get altered due to differences in species numbers and diversity although there are no alterations in the environment.
- c. In both the experiments, the ecosystem is recreated which may alter the dynamics of the ecosystem the experiments are aiming to analyze.
- d. Altering a natural ecosystem through partitioning, which occurs in both the experiments may change its dynamics due to differences in species numbers and diversity.

**25.** If a scientist wanted to monitor a desert food chain, what type of model might they develop and why?

- a. An analytical model would be ideal because they can address simple, linear ecosystem components that are mathematically complex.
- b. A simulation model would be ideal because they can address simple, linear systems that are mathematically complex.
- c. An analytical model would be ideal as they are considered ecologically more realistic than any other model.
- d. A simulation model would be ideal because it uses numerical techniques to solve problems and visualize the complex relationships that exist in the ecosystem.

**26.** Compare and contrast food chains and food webs. What are the strengths of each concept in describing ecosystems?

- a. Both food chain and food web follow a single path as energy is transferred in an ecosystem. Food chains are easier to follow and experiment with but less accurate whereas food webs are more holistic and complex.
- b. Both food web and food chain describe energy transfer dynamics in an ecosystem. Food chains are non-linear systems which are easier to follow and experiment with whereas food webs are linear, holistic and can be directly used as input for simulation models.
- c. Both food chain and food web follow a single path as energy is transferred in an ecosystem. Food chains are linear systems, easier to follow and used directly as input for simulation models, whereas food webs are non-linear, accurate, holistic and flexible for analytical modeling.
- d. Both food web and food chain describe energy transfer dynamics in an ecosystem. Food chains are linear systems, easier to follow and experiment with whereas food webs are non-linear, accurate and holistic and can be directly used as input for simulation models.

**27.** Name one natural and one human-related type of disturbance. Why are they of concern to conservationists?

- a. Lightening is a type of natural disturbance whereas pollution is a human related disturbance. Both are of concern to conservationists because they affect the entire ecosystem.
- b. Fire is a type of natural disturbances whereas agriculture is a human related disturbance. Both types are of concern to conservationists because ecosystems cannot bounce back from a disturbance.
- c. Pollution is a type of natural disturbance whereas lightening is a human related disturbance. Both are of concern to conservationists because they alter ecosystems.
- d. Lightening is a type of natural disturbance whereas pollution is a human related disturbance. Both are of concern to conservationists because they alter ecosystems.

**28.** Compare grazing and detrital food webs. Why would they both be present in the same ecosystem?

- a. The primary producers of detrital food webs are decomposers whereas those of grazing food webs are non-photosynthetic. Both primary producers support different components of the ecosystem.
  - b. The primary producers of detrital food webs are photosynthetic whereas those of grazing food webs are decomposers. Both primary producers support different components of the ecosystem.
  - c. The primary producers of detrital food webs are decomposers whereas those of grazing food webs are photosynthetic. Both primary producers support different components of the ecosystem.
  - d. The primary producers of detrital food webs are chemoautotrophs whereas those of grazing food webs are photosynthetic. Both primary producers support different components of the ecosystem.
- 29.** How does the amount of food that endotherms and ectotherms consume compare with their net production efficiency (NPE)?
- a. The amount of food eaten by an animal does not affect its net production efficiency (NPE).
  - b. Endotherms use more energy compared to ectotherms due to energy loss by respiration and heat.
  - c. Both endotherms and ectotherms use the same energy from food.
  - d. Ectotherms use more energy compared to endotherms due to energy loss by respiration and heat.
- 30.** Compare the three types of ecosystem pyramids and how well they describe ecosystem structure. Identify which ones can be inverted and give a specific example of an inverted pyramid for each.
- a. The three types of ecosystem pyramids are pyramids of energy, number and biomass out of which number and energy pyramids can be inverted. Examples of inverted pyramids of number and energy are temperate forests in summer and phytoplankton in the English Channel respectively.
  - b. The three types of ecosystem pyramids are pyramids of energy, number and biomass out of which number and biomass pyramids can be inverted. Examples of inverted pyramids of number and biomass are temperate forests in summer and phytoplankton in the English Channel respectively.
  - c. The three types of ecosystem pyramids are pyramids of energy, number and biomass out of which number and biomass pyramids can be inverted. Examples of inverted pyramids of number and biomass are temperate forests in summer and Silver Springs ecosystem in Florida respectively.
  - d. The three types of ecosystem pyramids are pyramids of energy, number and biomass out of which number and biomass pyramids can be inverted. Examples of inverted pyramids of number and biomass are grasslands in summer and phytoplankton in the English Channel respectively.
- 31.** Why do scientists more commonly analyze net primary productivity compared with gross primary productivity?
- a. Net primary productivity incorporates features like production at present and next trophic levels, whereas gross primary productivity does not.
  - b. Net primary productivity is the rate at which photosynthetic primary producers incorporate energy from the sun.
  - c. As net primary productivity is the energy content available to the organisms of the next trophic level.
  - d. As respiration and heat loss uses energy of the primary producer, therefore, net primary productivity is what is actually available to primary consumers.
- 32.** Describe nitrogen fixation and why it is important to agriculture.

- a. The process of nitrate formation from ammonia is called nitrogen fixation. It improves agricultural production as nitrogen is required by plants for nucleotide and protein formation.
- b. The process of nitrogen being bonded to organic molecule is called nitrogen fixation. It improves the crop yield by allowing the plants to compete with weeds.
- c. The reduction of nitrates back to nitrogen gas is called nitrogen fixation. It improves agricultural production as nitrogen is required by plants for nucleotide and protein formation.
- d. The process of nitrogen being bonded into organic molecules is called nitrogen fixation. It improves agricultural production as nitrogen is required by plants for nucleotide and protein formation.

**33.** How do agricultural animals such as cattle raise atmospheric carbon levels? What is a side effect?

- a. Cattle produce carbon monoxide, which when inhaled can cause death.
- b. Cattle produce carbon monoxide, which is a major contributor to global warming.
- c. Agricultural animals increase the amount of greenhouse gases by producing carbon dioxide and methane, so they contribute to global warming.
- d. Agricultural animals increase the amount of greenhouse gases by producing ozone, which contributes to global warming.

**34.** What form of sulfur is found in the atmosphere and how does it leave the atmosphere?

- a. hydrogen sulfide, which leaves the atmosphere as weak sulfur dioxide rain
- b. sulfur dioxide, which leaves the atmosphere as weak sulfur dioxide rain
- c. hydrogen sulfide, which leaves the atmosphere as weak sulfuric acid rain
- d. sulfur dioxide, which leaves the atmosphere as weak sulfuric acid rain

## TEST PREP FOR AP® COURSES

**35.** Producers and consumers are necessary for ecosystem function and for energy to pass through an ecosystem. What might happen in an aquatic system with excess producers relative to consumers?

- a. Oxygen depletion would result in dieoff.
- b. There would be no basal energy source.
- c. Carbon cannot be sequestered.
- d. There would be more undigestable animal parts.

**36.** Energy is a fundamental component in an ecosystem and is contributed by the primary producers. Describe how light energy can, in turn, support the consumers of an ecosystem.

- a. Light energy is converted by primary producers and primary consumers. Consumers belonging to higher trophic levels feed on them to gain energy.
- b. Primary producers can only obtain energy from sunlight by photosynthesis and gain energy by feeding on them or other consumers which have consumed these producers.
- c. Primary producers convert light energy by photosynthesis and consumers gain energy by feeding on them or other consumers which have consumed these producers.
- d. Primary producers convert light energy through chemosynthesis and consumers gain energy by feeding on them or other consumers which have consumed these producers.

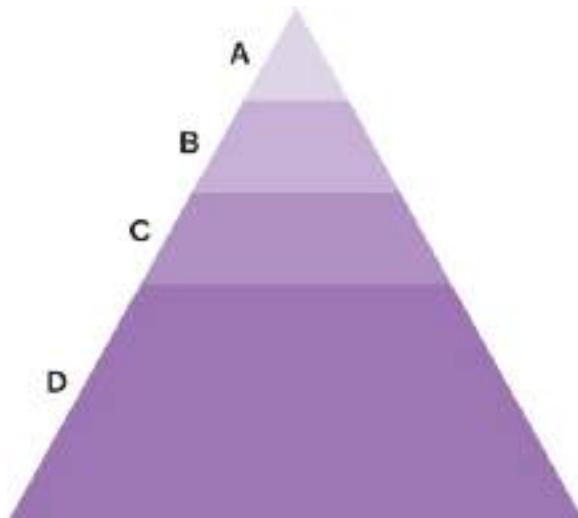

**37.** In a microcosm experiment using fish tanks to mimic a lake environment, an increase in the number of stickleback species would increase the dissolved organic carbon particle size. How could this affect primary producers in the ecosystem?

- a. enhance growth rate
- b. increase abundance
- c. decrease abundance
- d. maintain growth rate

**38.** Studies on stickleback fish revealed that the presence of two species of stickleback reduced the amount of algal

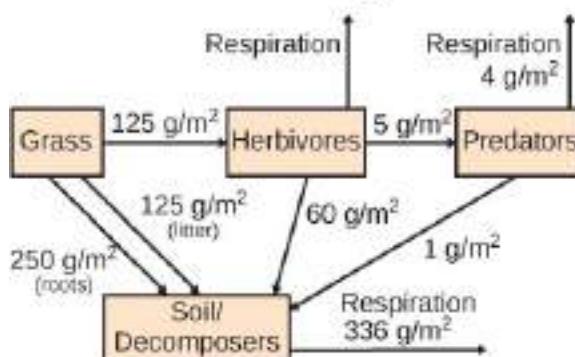

blooms relative to the presence of one species of stickleback in a microcosm experiment. How does this occur?

- This occurred as the presence of two species caused an increase in dissolved organic carbon molecule size, which blocked the penetration of light in water and prevented algal photosynthesis.
  - This occurred because two stickleback species consumed all the nutrients which prevented algae from being able to grow.
  - This occurred because dissolved organic carbon molecule size increased in the presence of one fish species which increased the amount of algal blooms.
  - This occurred as algae are consumed in more amounts in the presence of two stickleback species.
- 39.** This figure depicts energy exchange through trophic levels. Which level represents the primary producers?

- A
  - B
  - C
  - D
- 40.**

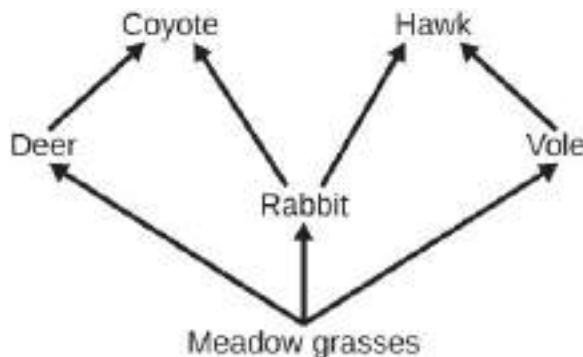

### Carbon Flow in a Grassland Ecosystem

How much carbon ( $\text{g}/\text{m}^2$ ) is released into the atmosphere as a result of the metabolic activity of herbivores? Give your answer to the nearest whole number.

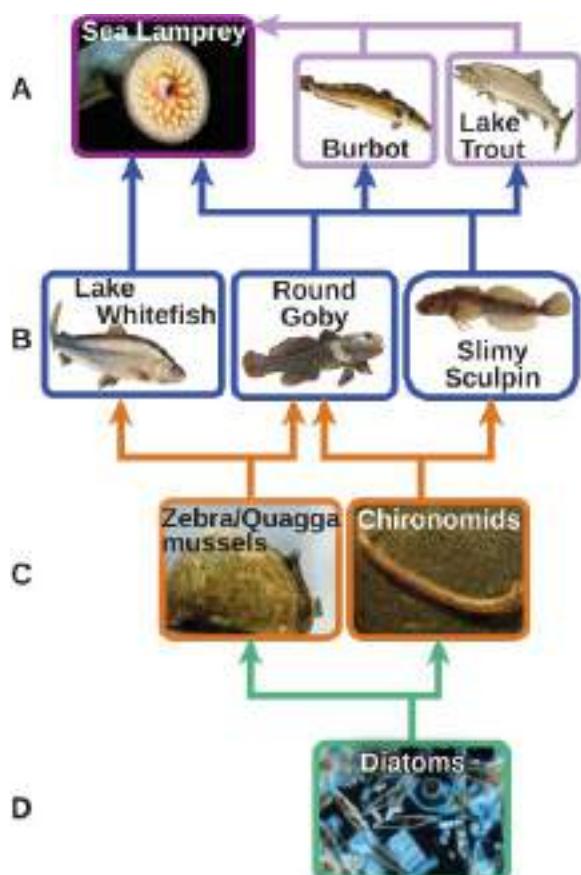

- 125  $\text{g}/\text{m}^2$  carbon is released into the atmosphere as a result of the metabolic activity of herbivores.
- 65  $\text{g}/\text{m}^2$  carbon is released into the atmosphere as a result of the metabolic activity of herbivores.
- 60  $\text{g}/\text{m}^2$  carbon is released into the atmosphere as a result of the metabolic activity of herbivores.
- 5  $\text{g}/\text{m}^2$  carbon is released into the atmosphere as a result of the metabolic activity of herbivores.

- 41.** The following is a food web for a meadow habitat that occupies  $25.6 \text{ km}^2$ . The primary producers' biomass is uniformly distributed throughout the habitat and totals  $1,500 \text{ kg}/\text{km}^2$ . Developers have approved a project that will permanently reduce the primary producers' biomass by 50 percent and remove all rabbits and deer. Which of the following is the most likely result at the completion of the project?

- The biomass of coyotes will be 6 kg, and the biomass of hawks will be 0.5 kg.
- The biomass of coyotes will be dramatically reduced.
- The coyotes will switch prey preferences and outcompete the hawks.
- There will be 50 percent fewer voles and 90 percent fewer hawks.

42.

This figure shows a food web of an ecosystem. What would happen to the food web if all of the species of the entire row B was wiped out by a natural disaster such as an oil spill? Why?

- The producers may die out, causing the food web to collapse.
- The food web would not be affected as the secondary and tertiary consumers would become primary and secondary consumers, respectively.
- The tertiary consumers would die out due to lack of food and this could potentially lead to collapse of the entire food web.
- The food web might suffer from loss of primary producers for a while which would then recover quickly, thus, reviving the ecosystem.

43. Humans are very active in modifying ecosystems

worldwide. If a new set of buildings on the edge of a forest block sunlight from reaching the majority of one part of the forest, what might happen to that part of the forest?

- Herbivores would occur in high abundance.
- Plants would occur in high abundance.
- Everything would remain the same.
- Herbivores would occur in low abundance.

44. If you examined predator-prey relationships within an ecosystem and noticed that the removal of predators also resulted in the die-off of herbivores, what would you suspect occurred?

- Removal of predators would directly lower the number of herbivores.
- The lack of predators could mean that too much primary production occurred.
- Herbivores from another region may have entered the ecosystem and consumed the primary producers, causing death of the original herbivores species.
- Overeating by herbivores could have caused depletion of the primary producers, leaving the herbivores without enough food.

45. Although producers are essential for energy to flow into an ecosystem, consumers also have important roles. What might happen in an aquatic system with excess consumers relative to producers?

- Oxygen depletion would result in dieoff.
- There would be an excess of the basal energy source.
- Consumers would deplete the abundance of producers.
- There would be more undigestable animal parts.

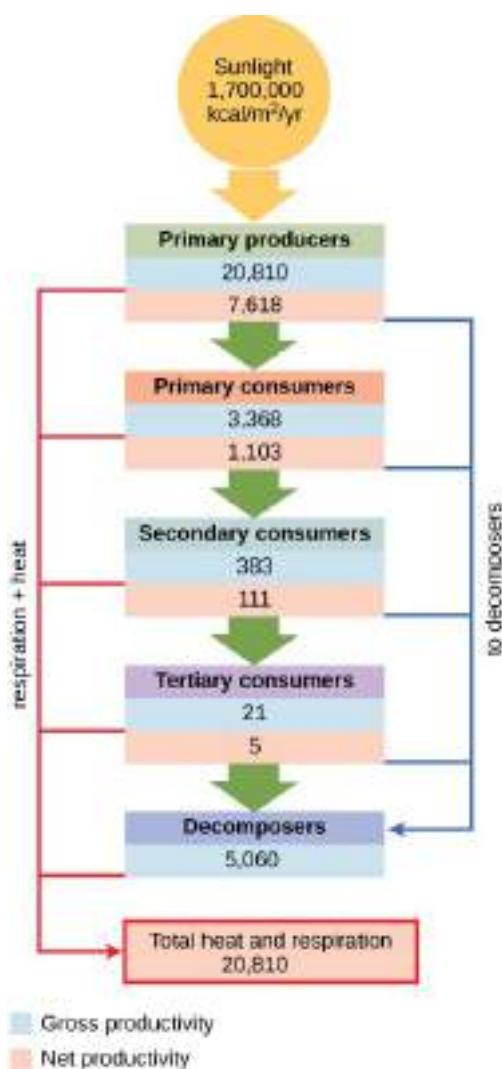

46. The following is the equation for trophic level transfer efficiency:  $(\text{production at present trophic level}/\text{production at past trophic level}) \times 100$ . If primary producers produce  $1600 \text{ kcal/m}^2$ , and primary consumers have  $900 \text{ kcal/m}^2$ , what is the trophic level transfer efficiency?

- 50
- 200
- 800
- 1600

47. There are four trophic levels in a food chain and the amount of energy at the trophic level of the primary producer is  $33,000 \text{ kcal/m}^2$ . Which of the following represents the amount of energy of the tertiary consumer?

- $75 \text{ kcal/m}^2$
- $500 \text{ kcal/m}^2$
- $11,000 \text{ kcal/m}^2$
- $33,000 \text{ kcal/m}^2$

- 48.** Why does this figure show a higher value of gross productivity for the decomposers than the tertiary consumers?

- Due to the difference in conversion efficiencies of decomposers and tertiary consumers.
- Because large animals are tertiary consumers whereas small microorganisms are decomposers.
- Because tertiary consumers only consume secondary consumers whereas decomposers consume dead components of each trophic level.
- Because tertiary consumers only consume primary consumers whereas decomposers consume dead components of each trophic level.

- 49.** One of the key concerns about global climate change is excess amounts of carbon being released into the atmosphere. There are, however, some ways in which carbon can be sequestered from the atmosphere. Which of the following is a natural process that promotes carbon sequestration?

- burning fossil fuels
- methane from cattle
- photosynthesis by plants
- volcanic eruption

## SCIENCE PRACTICE CHALLENGE QUESTIONS

- 50.** The food web shown below utilizes an arrow pointing from a species feeds on another to indicate the trophic structure of a simplified estuarine ecosystem at the boundary between the ocean and the shore.

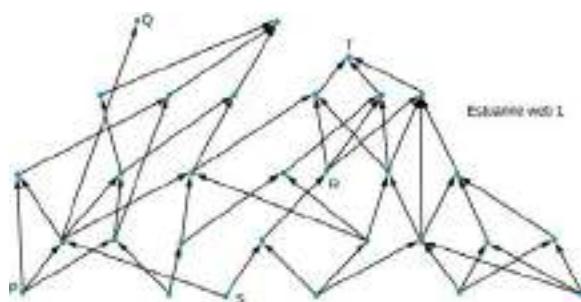

Figure 37.24

- Analyze** the interactions among species and indicate primary producers by circling the node in the food web. **Identify** the primary producers by circling the nodes in the food web.
- Predict** quantitatively how free energy availability for a top species such as the one designated as T in the web changes if it feeds directly on S, assuming the abundance of species S is limited only by radiant energy input.
- Consider the consequences of the dietary shift described in B if the abundance of species becomes depleted due to consumption by species T. Under those circumstances **refine** your analysis of the food web to describe the potential effect on species Q and R.
- Based on the preceding analyses, **construct a claim** regarding the effect of the structure, in terms of biodiversity and number of interactions among species, on

ecosystem stability.

# 38 | CONSERVATION BIOLOGY AND BIODIVERSITY

**Figure 38.1** Lake Victoria in Africa, shown in this satellite image, was the site of one of the most extraordinary evolutionary findings on the planet, as well as a casualty of devastating biodiversity loss. (credit: modification of work by Rishabh Tatiraju, using NASA World Wind software)

## Chapter Outline

- 38.1: The Biodiversity Crisis**
- 38.2: The Importance of Biodiversity to Human Life**
- 38.3: Threats to Biodiversity**
- 38.4: Preserving Biodiversity**

## Introduction

In the 1980s, biologists working in Lake Victoria in Africa discovered one of the most extraordinary products of evolution on the planet. Located in the Great Rift Valley, Lake Victoria is a large lake about 68,900 km<sup>2</sup> in area (larger than Lake Huron, the second largest of North America's Great Lakes). Biologists were studying species of a family of fish called cichlids. They found that as they sampled for fish in different locations of the lake, they never stopped finding new species, and they identified nearly 500 evolved types of cichlids. But while studying these variations, they quickly discovered that the invasive Nile Perch was destroying the lake's cichlid population, bringing hundreds of cichlid species to extinction with devastating rapidity. You can read more about the new species of cichlids at the [Science Daily website](http://openstaxcollege.org/l/32dreampond) (<http://openstaxcollege.org/l/32dreampond>) .

## 38.1 | The Biodiversity Crisis

In this section, you will explore the following questions:

- What are the different types of biodiversity?
- Why can biodiversity be described as the equilibrium of naturally fluctuating rates of extinction and speciation?
- What are examples of historical causes of high extinction rates in Earth's history?

### Connection for AP® Courses

We have come to the last chapter in the text, and the journey has taken us from the origin of life on Earth to the exploration of the myriad and diverse organisms that currently inhabit our planet. Although some information in this chapter is not in scope for AP®, we must recognize how the activities of our own species, *Home sapiens*, impact ecosystems and the species inhabiting them. By appreciating and protecting other species, we preserve our own. The inverse is also true.

The exact number and kinds of species on Earth is unknown, but scientists estimate that there are about 8.7 million eukaryotic species, with only 1.5 million identified, named, and studied. The number of prokaryotes far exceeds these numbers. **Biodiversity** describes the number and variety of organisms in the biosphere.

We have learned that evolution and speciation continue to occur, but Earth has experienced five mass **extinctions**—the elimination of major groups of species. For AP® you do not need to know the names, dates and causes of these extinctions; however understanding them will help you understand how biodiversity has changed over time.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 1 and Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

|                                   |                                                                                                                                                                                       |
|-----------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Big Idea 1</b>                 | The process of evolution drives the diversity and unity of life.                                                                                                                      |
| <b>Enduring Understanding 1.C</b> | Life continues to evolve within a changing environment.                                                                                                                               |
| <b>Essential Knowledge</b>        | <b>1.C.1</b> Speciation and extinction have occurred throughout Earth's history.                                                                                                      |
| <b>Science Practice</b>           | <b>5.1</b> The student can analyze data to identify patterns or relationships.                                                                                                        |
| <b>Learning Objective</b>         | <b>1.20</b> The student is able to analyze data related to questions of speciation and extinction throughout the Earth's history.                                                     |
| <b>Essential Knowledge</b>        | <b>1.C.1</b> Speciation and extinction have occurred throughout Earth's history.                                                                                                      |
| <b>Science Practice</b>           | <b>4.2</b> The student can design a plan for collecting data to answer a particular scientific question.                                                                              |
| <b>Learning Objective</b>         | <b>1.21</b> The student is able to design a plan for collecting data to investigate the scientific claim that speciation and extinction have occurred throughout the Earth's history. |
| <b>Big Idea 4</b>                 | Biological systems interact, and these systems and their interactions possess complex properties.                                                                                     |
| <b>Enduring Understanding 4.B</b> | Competition and cooperation are important aspects of biological systems.                                                                                                              |

|                            |                                                                                                                                                                                    |
|----------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

| <b>Learning Objective</b>  | <b>4.20</b> The student is able to explain how the distribution of ecosystems changes over time by identifying large-scale events that have resulted in these changes in the past. |

Traditionally, ecologists have measured biodiversity by taking into account both the number of species and their commonness. Biodiversity can be estimated at a number of levels of organization of living things. These estimation indexes, which came from information theory, are most useful as a first step in quantifying biodiversity between and within ecosystems; they are less useful when the main concern among conservation biologists is simply the loss of biodiversity. However, biologists recognize that measures of biodiversity, in terms of species diversity, may help focus efforts to preserve the biologically or technologically important elements of biodiversity.

The Lake Victoria cichlids provide an example through which we can begin to understand biodiversity. The biologists studying cichlids in the 1980s discovered hundreds of cichlid species representing a variety of specializations to particular habitat types and specific feeding strategies: eating plankton floating in the water, scraping and then eating algae from rocks, eating insect larvae from the bottom, and eating the eggs of other species of cichlid. The cichlids of Lake Victoria are the product of an **adaptive radiation**. An adaptive radiation is a rapid (less than three million years in the case of the Lake Victoria cichlids) branching through speciation of a phylogenetic tree into many closely related species; typically, the species “radiate” into different habitats and niches. The Galápagos finches are an example of a modest adaptive radiation with 15 species. The cichlids of Lake Victoria are an example of a spectacular adaptive radiation that includes about 500 species.

At the time biologists were making this discovery, some species began to quickly disappear. A culprit in these declines was a species of large fish that was introduced to Lake Victoria by fisheries to feed the people living around the lake. The Nile perch was introduced in 1963, but lay low until the 1980s when its populations began to surge. The Nile perch population grew by consuming cichlids, driving species after species to the point of extinction (the disappearance of a species). In fact, there were several factors that played a role in the extinction of perhaps 200 cichlid species in Lake Victoria: the Nile perch, declining lake water quality due to agriculture and land clearing on the shores of Lake Victoria, and increased fishing pressure. Scientists had not even catalogued all of the species present—so many were lost that were never named. The diversity is now a shadow of what it once was.

The cichlids of Lake Victoria are a thumbnail sketch of contemporary rapid species loss that occurs all over Earth and is caused by human activity. Extinction is a natural process of macroevolution that occurs at the rate of about one out of 1 million species becoming extinct per year. The fossil record reveals that there have been five periods of mass extinction in history with much higher rates of species loss, and the rate of species loss today is comparable to those periods of mass extinction. However, there is a major difference between the previous mass extinctions and the current extinction we are experiencing: human activity. Specifically, three human activities have a major impact: destruction of habitat, introduction of exotic species, and over-harvesting. Predictions of species loss within the next century, a tiny amount of time on geological timescales, range from 10 percent to 50 percent. Extinctions on this scale have only happened five other times in the history of the planet, and they have been caused by cataclysmic events that changed the course of the history of life in each instance. Earth is now in one of those times.

## Types of Biodiversity

Scientists generally accept that the term biodiversity describes the number and kinds of species in a location or on the planet. Species can be difficult to define, but most biologists still feel comfortable with the concept and are able to identify and count eukaryotic species in most contexts. Biologists have also identified alternate measures of biodiversity, some of which are important for planning how to preserve biodiversity.

**Genetic diversity** is one of those alternate concepts. Genetic diversity or variation is the raw material for adaptation in a species. A species' future potential for adaptation depends on the genetic diversity held in the genomes of the individuals in populations that make up the species. The same is true for higher taxonomic categories. A genus with very different types of species will have more genetic diversity than a genus with species that look alike and have similar ecologies. If there were a choice between one of these genera of species being preserved, the one with the greatest potential for subsequent evolution is the most genetically diverse one. It would be ideal not to have to make such choices, but increasingly this may be the norm.

Many genes code for proteins, which in turn carry out the metabolic processes that keep organisms alive and reproducing. Genetic diversity can be measured as **chemical diversity** in that different species produce a variety of chemicals in their cells, both the proteins as well as the products and byproducts of metabolism. This chemical diversity has potential benefit for humans as a source of pharmaceuticals, so it provides one way to measure diversity that is important to human health and welfare.

Humans have generated diversity in domestic animals, plants, and fungi. This diversity is also suffering losses because of migration, market forces, and increasing globalism in agriculture, especially in heavily populated regions such as China, India, and Japan. The human population directly depends on this diversity as a stable food source, and its decline is troubling biologists and agricultural scientists.

It is also useful to define **ecosystem diversity**, meaning the number of different ecosystems on the planet or in a given geographic area (**Figure 38.2**). Whole ecosystems can disappear even if some of the species might survive by adapting to other ecosystems. The loss of an ecosystem means the loss of interactions between species, the loss of unique features of coadaptation, and the loss of biological productivity that an ecosystem is able to create. An example of a largely extinct ecosystem in North America is the prairie ecosystem. Prairies once spanned central North America from the boreal forest in northern Canada down into Mexico. They are now all but gone, replaced by crop fields, pasture lands, and suburban sprawl. Many of the species survive, but the hugely productive ecosystem that was responsible for creating the most productive agricultural soils is now gone. As a consequence, soils are disappearing or must be maintained at greater expense.

**Figure 38.2** The variety of ecosystems on Earth—from (a) coral reef to (b) prairie—enables a great diversity of species to exist. (credit a: modification of work by Jim Maragos, USFWS; credit b: modification of work by Jim Minnerath, USFWS)

### Current Species Diversity

Despite considerable effort, knowledge of the species that inhabit the planet is limited. A recent estimate suggests that the eukaryote species for which science has names, about 1.5 million species, account for less than 20 percent of the total number of eukaryote species present on the planet (8.7 million species, by one estimate). Estimates of numbers of

prokaryotic species are largely guesses, but biologists agree that science has only begun to catalog their diversity. Even with what is known, there is no central repository of names or samples of the described species; therefore, there is no way to be sure that the 1.5 million descriptions is an accurate number. It is a best guess based on the opinions of experts in different taxonomic groups. Given that Earth is losing species at an accelerating pace, science is very much in the place it was with the Lake Victoria cichlids: knowing little about what is being lost. **Table 38.1** presents recent estimates of biodiversity in different groups.

### Estimates of the Numbers of Described and Predicted Species by Taxonomic Group

**Table 38.1**

There are various initiatives to catalog described species in accessible ways, and the internet is facilitating that effort. Nevertheless, it has been pointed out that at the current rate of species description, which according to the State of Observed Species Report is 17,000 to 20,000 new species per year, it will take close to 500 years to finish describing life on this planet.<sup>[4]</sup> Over time, the task becomes both increasingly impossible and increasingly easier as extinction removes species from the planet.

Naming and counting species may seem an unimportant pursuit given the other needs of humanity, but it is not simply an accounting. Describing species is a complex process by which biologists determine an organism's unique characteristics and whether or not that organism belongs to any other described species. It allows biologists to find and recognize the species after the initial discovery, and allows them to follow up on questions about its biology. In addition, the unique characteristics of each species make it potentially valuable to humans or other species on which humans depend. Understanding these characteristics is the value of finding and naming species.

#### Patterns of Biodiversity

Biodiversity is not evenly distributed on Earth. Lake Victoria contained almost 500 species of cichlids alone, ignoring the other fish families present in the lake. All of these species were found only in Lake Victoria; therefore, the 500 species of cichlids were endemic. **Endemic species** are found in only one location. Endemics with highly restricted distributions are particularly vulnerable to extinction. Higher taxonomic levels, such as genera and families, can also be endemic. Lake Huron contains about 79 species of fish, all of which are found in many other lakes in North America. What accounts for the difference in fish diversity in these two lakes? Lake Victoria is a tropical lake, while Lake Huron is a temperate lake. Lake Huron in its present form is only about 7,000 years old, while Lake Victoria in its present form is about 15,000 years old. Biogeographers have suggested these two factors, latitude and age, are two of several hypotheses to explain biodiversity patterns on the planet.

# Career CONNECTION

## Biogeographer

Biogeography is the study of the distribution of the world's species—both in the past and in the present. The work of biogeographers is critical to understanding our physical environment, how the environment affects species, and how environmental changes impact the distribution of a species; it has also been critical to developing evolutionary theory. Biogeographers need to understand both biology and ecology. They also need to be well-versed in evolutionary studies, soil science, and climatology.

There are three main fields of study under the heading of biogeography: ecological biogeography, historical biogeography (called paleobiogeography), and conservation biogeography. Ecological biogeography studies the current factors affecting the distribution of plants and animals. Historical biogeography, as the name implies, studies the past distribution of species. Conservation biogeography, on the other hand, is focused on the protection and restoration of species based upon known historical and current ecological information. Each of these fields considers both zoogeography and phytogeography—the past and present distribution of animals and plants.

One of the oldest observed patterns in ecology is that species biodiversity in almost every taxonomic group increases as latitude declines. In other words, biodiversity increases closer to the equator (**Figure 38.3**).

**Figure 38.3** This map illustrates the number of amphibian species across the globe and shows the trend toward higher biodiversity at lower latitudes. A similar pattern is observed for most taxonomic groups.

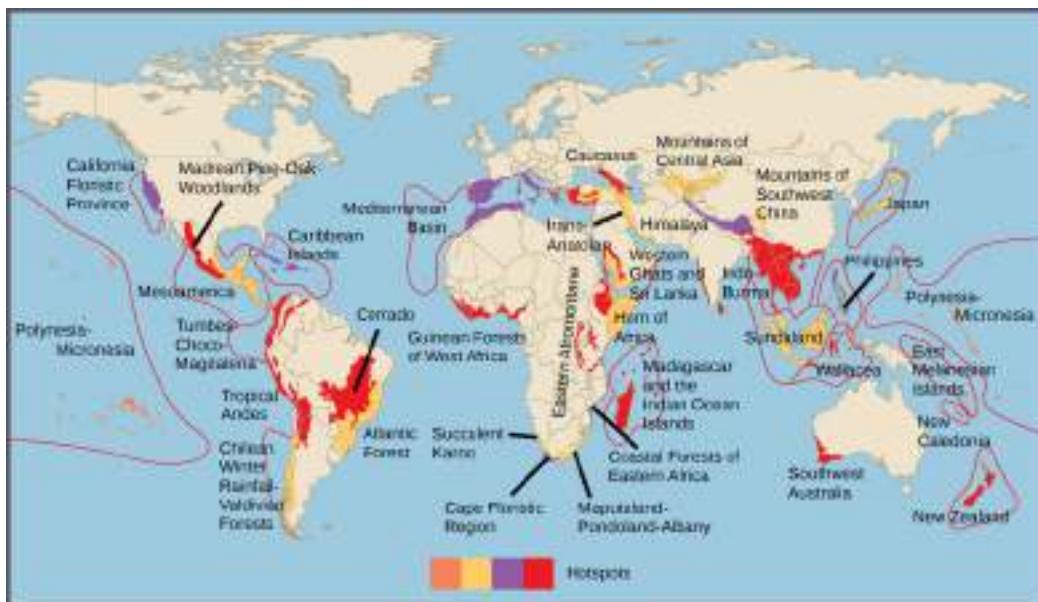

It is not yet clear why biodiversity increases closer to the equator, but hypotheses include the greater age of the ecosystems in the tropics versus temperate regions that were largely devoid of life or drastically impoverished during the last glaciation. The idea is that greater age provides more time for speciation. Another possible explanation is the increased energy the tropics receive from the sun versus the decreased energy that temperate and polar regions receive. It is not entirely clear how greater energy input could translate into more species. The complexity of tropical ecosystems may promote speciation by increasing the **heterogeneity**, or number of ecological niches, in the tropics relative to higher latitudes. The greater heterogeneity provides more opportunities for coevolution, specialization, and perhaps greater selection pressures leading to population differentiation. However, this hypothesis suffers from some circularity—ecosystems with more species encourage speciation, but how did they get more species to begin with? The tropics have been perceived as being more stable than temperate regions, which have a pronounced climate and day-length seasonality. The tropics have their own forms of seasonality, such as rainfall, but they are generally assumed to be more stable environments and this stability might promote speciation.

Regardless of the mechanisms, it is certainly true that all levels of biodiversity are greatest in the tropics. Additionally, the

rate of endemism is highest, and there are more biodiversity hotspots. However, this richness of diversity also means that knowledge of species is lowest, and there is a high potential for biodiversity loss.

### **Conservation of Biodiversity**

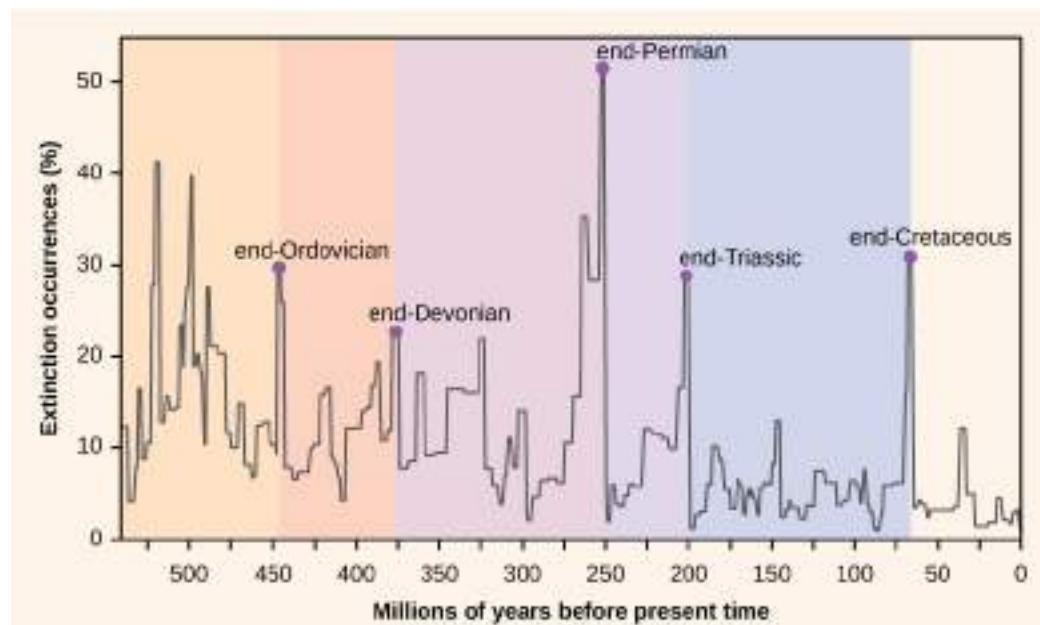

In 1988, British environmentalist Norman Myers developed a conservation concept to identify areas rich in species and at significant risk for species loss: biodiversity hotspots. **Biodiversity hotspots** are geographical areas that contain high numbers of endemic species. The purpose of the concept was to identify important locations on the planet for conservation efforts, a kind of conservation triage. By protecting hotspots, governments are able to protect a larger number of species. The original criteria for a hotspot included the presence of 1500 or more endemic plant species and 70 percent of the area disturbed by human activity. There are now 34 biodiversity hotspots (**Figure 38.4**) containing large numbers of endemic species, which include half of Earth's endemic plants.

**Figure 38.4** Conservation International has identified 34 biodiversity hotspots, which cover only 2.3 percent of the Earth's surface but have endemic to them 42 percent of the terrestrial vertebrate species and 50 percent of the world's plants.

### **Biodiversity Change through Geological Time**

The number of species on the planet, or in any geographical area, is the result of an equilibrium of two evolutionary processes that are ongoing: speciation and extinction. Both are natural “birth” and “death” processes of macroevolution. When speciation rates begin to outstrip extinction rates, the number of species will increase; likewise, the number of species will decrease when extinction rates begin to overtake speciation rates. Throughout Earth’s history, these two processes have fluctuated—sometimes leading to dramatic changes in the number of species on Earth as reflected in the fossil record (**Figure 38.5**).

**Figure 38.5** Percent extinction occurrences as reflected in the fossil record have fluctuated throughout Earth's history. Sudden and dramatic losses of biodiversity, called mass extinctions, have occurred five times.

Paleontologists have identified five strata in the fossil record that appear to show sudden and dramatic (greater than half of all extant species disappearing from the fossil record) losses in biodiversity. These are called mass extinctions. There are many lesser, yet still dramatic, extinction events, but the five mass extinctions have attracted the most research. An argument can be made that the five mass extinctions are only the five most extreme events in a continuous series of large extinction events throughout the Phanerozoic (since 542 million years ago). In most cases, the hypothesized causes are still controversial; however, the most recent event seems clear.

### The Five Mass Extinctions

The fossil record of the mass extinctions was the basis for defining periods of geological history, so they typically occur at the transition point between geological periods. The transition in fossils from one period to another reflects the dramatic loss of species and the gradual origin of new species. These transitions can be seen in the rock strata. **Table 38.2** provides data on the five mass extinctions.

### Mass Extinctions

| Geological Period    | Mass Extinction Name      | Time (millions of years ago) |
|----------------------|---------------------------|------------------------------|
| Ordovician–Silurian  | end-Ordovician O–S        | 450–440                      |
| Late Devonian        | end-Devonian              | 375–360                      |
| Permian–Triassic     | end-Permian               | 251                          |
| Triassic–Jurassic    | end-Triassic              | 205                          |
| Cretaceous–Paleogene | end-Cretaceous K–Pg (K–T) | 65.5                         |

**Table 38.2** This table shows the names and dates for the five mass extinctions in Earth's history.

The Ordovician-Silurian extinction event is the first recorded mass extinction and the second largest. During this period, about 85 percent of marine species (few species lived outside the oceans) became extinct. The main hypothesis for its cause is a period of glaciation and then warming. The extinction event actually consists of two extinction events separated by about 1 million years. The first event was caused by cooling, and the second event was due to the subsequent warming. The climate changes affected temperatures and sea levels. Some researchers have suggested that a gamma-ray burst, caused by a nearby supernova, is a possible cause of the Ordovician-Silurian extinction. The gamma-ray burst would have stripped away

the Earth's ozone layer causing intense ultraviolet radiation from the sun and may account for climate changes observed at the time. The hypothesis is speculative, but extraterrestrial influences on Earth's history are an active line of research. Recovery of biodiversity after the mass extinction took from 5 to 20 million years, depending on the location.

The late Devonian extinction may have occurred over a relatively long period of time. It appears to have affected marine species and not the plants or animals inhabiting terrestrial habitats. The causes of this extinction are poorly understood.

The end-Permian extinction was the largest in the history of life. Indeed, an argument could be made that Earth nearly became devoid of life during this extinction event. The planet looked very different before and after this event. Estimates are that 96 percent of all marine species and 70 percent of all terrestrial species were lost. It was at this time, for example, that the trilobites, a group that survived the Ordovician–Silurian extinction, became extinct. The causes for this mass extinction are not clear, but the leading suspect is extended and widespread volcanic activity that led to a runaway global-warming event. The oceans became largely anoxic, suffocating marine life. Terrestrial tetrapod diversity took 30 million years to recover after the end-Permian extinction. The Permian extinction dramatically altered Earth's biodiversity makeup and the course of evolution.

The causes of the Triassic–Jurassic extinction event are not clear and hypotheses of climate change, asteroid impact, and volcanic eruptions have been argued. The extinction event occurred just before the breakup of the supercontinent Pangaea, although recent scholarship suggests that the extinctions may have occurred more gradually throughout the Triassic.

The causes of the end-Cretaceous extinction event are the ones that are best understood. It was during this extinction event about 65 million years ago that the dinosaurs, the dominant vertebrate group for millions of years, disappeared from the planet (with the exception of a theropod clade that gave rise to birds). Indeed, every land animal that weighed more than 25 kg became extinct. The cause of this extinction is now understood to be the result of a cataclysmic impact of a large meteorite, or asteroid, off the coast of what is now the Yucatán Peninsula. This hypothesis, proposed first in 1980, was a radical explanation based on a sharp spike in the levels of iridium (which rains down from space in meteors at a fairly constant rate but is otherwise absent on Earth's surface) at the rock stratum that marks the boundary between the Cretaceous and Paleogene periods (**Figure 38.6**). This boundary marked the disappearance of the dinosaurs in fossils as well as many other taxa. The researchers who discovered the iridium spike interpreted it as a rapid influx of iridium from space to the atmosphere (in the form of a large asteroid) rather than a slowing in the deposition of sediments during that period. It was a radical explanation, but the report of an appropriately aged and sized impact crater in 1991 made the hypothesis more believable. Now an abundance of geological evidence supports the theory. Recovery times for biodiversity after the end-Cretaceous extinction are shorter, in geological time, than for the end-Permian extinction, on the order of 10 million years.

**visual CONNECTION**

**Figure 38.6** In 1980, Luis and Walter Alvarez, Frank Asaro, and Helen Michels discovered, across the world, a spike in the concentration of iridium within the sedimentary layer at the K-Pg boundary. These researchers hypothesized that this iridium spike was caused by an asteroid impact that resulted in the K-Pg mass extinction. In the photo, the iridium layer is the light band. (credit: USGS)

Scientists measured the relative abundance of fern spores above and below the Cretaceous-Paleogene boundary in a rock sample. Which of the following statements most likely represents their findings?

- a. An abundance of fern spores from several species was found above the Cretaceous-Paleogene boundary, but none were found below.
- b. Fern spores were found both above and below the Cretaceous-Paleogene boundary, but the spores were more abundant below the boundary than above the boundary.
- c. Many species of fern spores were found both above and below the boundary, but the total number of spores was greater above the boundary.
- d. An abundance of fern spores from several species was found below the Cretaceous-Paleogene boundary, but none were found above.

**LINK TO LEARNING**

Explore this **interactive website** (<http://openstaxcollege.org/l/extinctions>) about mass extinctions.

Why did the dinosaurs that survived the immediate impact of the meteorite also die off?

- a. The Earth became unbearably hot.
- b. Prolonged drought resulted from the meteorite impact.
- c. Debris in the atmosphere formed a thick cloud, which blocked the sun. Plants and animals died.
- d. A giant tsunami wiped out all the dinosaurs from the surface of the Earth.

### The Pleistocene Extinction

The Pleistocene Extinction is one of the lesser extinctions, and a recent one. It is well known that the North American, and to some degree Eurasian, **megafauna**, or large animals, disappeared toward the end of the last glaciation period. The extinction appears to have happened in a relatively restricted time period of 10,000–12,000 years ago. In North America, the losses were quite dramatic and included the woolly mammoths (last dated about 4,000 years ago in an isolated population), mastodon, giant beavers, giant ground sloths, saber-toothed cats, and the North American camel, just to name a few. The possibility that the rapid extinction of these large animals was caused by over-hunting was first suggested in the 1900s. Research into this hypothesis continues today. It seems likely that over-hunting caused many pre-written history extinctions in many regions of the world.

In general, the timing of the Pleistocene extinctions correlated with the arrival of humans and not with climate-change events, which is the main competing hypothesis for these extinctions. The extinctions began in Australia about 40,000 to 50,000 years ago, just after the arrival of humans in the area: a marsupial lion, a giant one-ton wombat, and several giant kangaroo species disappeared. In North America, the extinctions of almost all of the large mammals occurred 10,000–12,000 years ago. All that are left are the smaller mammals such as bears, elk, moose, and cougars. Finally, on many remote oceanic islands, the extinctions of many species occurred coincident with human arrivals. Not all of the islands had large animals, but when there were large animals, they were lost. Madagascar was colonized about 2,000 years ago and the large mammals that lived there became extinct. Eurasia and Africa do not show this pattern, but they also did not experience a recent arrival of humans. Humans arrived in Eurasia hundreds of thousands of years ago after the origin of the species in Africa. This topic remains an area of active research and hypothesizing. It seems clear that even if climate played a role, in most cases human hunting precipitated the extinctions.

### Present-Time Extinctions

The sixth, or Holocene, mass extinction appears to have begun earlier than previously believed and has mostly to do with the activities of *Homo sapiens*. Since the beginning of the Holocene period, there are numerous recent extinctions of individual species that are recorded in human writings. Most of these are coincident with the expansion of the European colonies since the 1500s.

One of the earlier and popularly known examples is the dodo bird. The dodo bird lived in the forests of Mauritius, an island in the Indian Ocean. The dodo bird became extinct around 1662. It was hunted for its meat by sailors and was easy prey because the dodo, which did not evolve with humans, would approach people without fear. Introduced pigs, rats, and dogs brought to the island by European ships also killed dodo young and eggs.

Steller's sea cow became extinct in 1768; it was related to the manatee and probably once lived along the northwest coast of North America. Steller's sea cow was first discovered by Europeans in 1741 and was hunted for meat and oil. The last sea cow was killed in 1768. That amounts to 27 years between the sea cow's first contact with Europeans and extinction of the species.

In 1914, the last living passenger pigeon died in a zoo in Cincinnati, Ohio. This species had once darkened the skies of North America during its migrations, but it was hunted and suffered from habitat loss through the clearing of forests for farmland. In 1918, the last living Carolina parakeet died in captivity. This species was once common in the eastern United States, but it suffered from habitat loss. The species was also hunted because it ate orchard fruit when its native foods were destroyed to make way for farmland. The Japanese sea lion, which inhabited a broad area around Japan and the coast of Korea, became extinct in the 1950s due to fishermen. The Caribbean monk seal was distributed throughout the Caribbean Sea but was driven to extinction via hunting by 1952.

These are only a few of the recorded extinctions in the past 500 years. The International Union for Conservation of Nature (IUCN) keeps a list of extinct and endangered species called the Red List. The list is not complete, but it describes 380 extinct species of vertebrates after 1500 AD, 86 of which were driven extinct by overhunting or overfishing.

### Estimates of Present-Time Extinction Rates

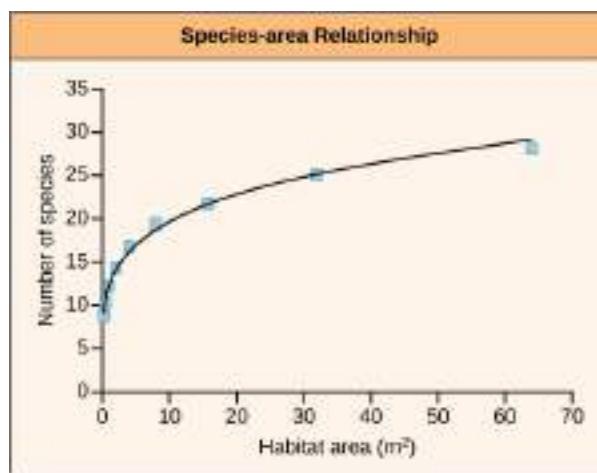

Estimates of **extinction rates** are hampered by the fact that most extinctions are probably happening without observation. The extinction of a bird or mammal is likely to be noticed by humans, especially if it has been hunted or used in some other way. But there are many organisms that are of less interest to humans (not necessarily of less value) and many that are undescribed.

The background extinction rate is estimated to be about one per million species per year (E/MSY). For example, assuming there are about ten million species in existence, the expectation is that ten species would become extinct each year (each year represents ten million species per year).

One contemporary extinction rate estimate uses the extinctions in the written record since the year 1500. For birds alone this method yields an estimate of 26 E/MSY. However, this value may be underestimated for three reasons. First, many species would not have been described until much later in the time period, so their loss would have gone unnoticed. Second, the

number of recently extinct species is increasing because extinct species now are being described from skeletal remains. And third, some species are probably already extinct even though conservationists are reluctant to name them as such. Taking these factors into account raises the estimated extinction rate closer to 100 E/MSY. The predicted rate by the end of the century is 1500 E/MSY.

A second approach to estimating present-time extinction rates is to correlate species loss with habitat loss by measuring forest-area loss and understanding species-area relationships. The **species-area relationship** is the rate at which new species are seen when the area surveyed is increased. Studies have shown that the number of species present increases as the size of the island increases. This phenomenon has also been shown to hold true in other habitats as well. Turning this relationship around, if the habitat area is reduced, the number of species living there will also decline. Estimates of extinction rates based on habitat loss and species-area relationships have suggested that with about 90 percent habitat loss an expected 50 percent of species would become extinct. Species-area estimates have led to species extinction rate calculations of about 1000 E/MSY and higher. In general, actual observations do not show this amount of loss and suggestions have been made that there is a delay in extinction. Recent work has also called into question the applicability of the species-area relationship when estimating the loss of species. This work argues that the species-area relationship leads to an overestimate of extinction rates. A better relationship to use may be the endemics-area relationship. Using this method would bring estimates down to around 500 E/MSY in the coming century. Note that this value is still 500 times the background rate.

**Figure 38.7** Studies have shown that the number of species present increases with the size of the habitat. (credit: modification of work by Adam B. Smith)

Check out this [interactive exploration](http://openstaxcollege.org/l/what_is_missing) ([http://openstaxcollege.org/l/what\\_is\\_missing](http://openstaxcollege.org/l/what_is_missing)) of endangered and extinct species, their ecosystems, and the causes of the endangerment or extinction.

Choose “What you can do” from the navigation menu at the left of the home page and answer the question: Why would eating less meat lead to biodiversity preservation?

- a. because livestock farming accounts for 40% of all deforestation, which reduces habitats for numerous species, leads to building up of greenhouse gases, soil erosion and increase in rainfall
- b. because livestock farming accounts for 40% of all deforestation, which reduces habitats for numerous species, leads to building up of greenhouse gases, soil erosion and decrease in rainfall
- c. because livestock farming accounts for 63% of all deforestation, which reduces habitats for numerous species, leads to building up of greenhouse gases, soil erosion and increase in rainfall
- d. because livestock farming accounts for 63% of all deforestation, which reduces habitats for numerous species and leads to a build up of greenhouse gases, soil erosion and decrease in rainfall

## science practices CONNECTION for AP<sup>®</sup> Courses

### Think About It

How have large-scale events results in changes in ecosystem dynamics? What are some hypotheses about the causes of mass extinctions? What types of evidence do scientists use to support these hypotheses? What particular evidence supports a specific event’s occurrence?

## 38.2 | The Importance of Biodiversity to Human Life

In this section, you will explore the following questions:

- How does chemical diversity benefit humans?
- What are components of biodiversity that support human agriculture?
- What are ecosystem services?

### Connection for AP<sup>®</sup> Courses

The information in this section does not directly apply to the concepts and content required for AP<sup>®</sup>. However, as students of biology, we need to understand the importance of preserving species and ecosystems before addressing why we should be concerned about the negative impacts of human activity on biodiversity ([Threats to Biodiversity](#))

The loss of an individual species, such as the passenger pigeon, dodo bird, or woolly mammoth, seems unimportant to the “big picture,” unless it’s the loss of a keystone species (see the chapter that discusses population and community ecology). Extinction is a normal part of macroevolution. However, accelerated extinction rates accompanied by the loss of tens of thousands of species and the collapse of ecosystems can affect human welfare. With respect to health, many medicines,

including aspirin, codeine, digoxin, atropine, and vincristine, are derived from plants. In recent years, animal venoms and toxins have excited researchers because of their pharmaceutical potential. Agricultural diversity is a requirement for food security, and the loss of wild relatives to crops threatens our ability to create new varieties that can grow in areas with previously impossible climates and soil conditions. Since 1990, global fish production has declined, and for approximately one billion of us, aquatic resources provide the main source of animal protein. Furthermore, who can put a number or monetary value on the psychological benefits of the natural landscapes we enjoy while vacationing and artists use for inspiration?

Information presented and examples highlighted in this section are not within the scope for AP<sup>®</sup> and do not align to the Curriculum Framework.

Agriculture began after early hunter-gatherer societies first settled in one place and heavily modified their immediate environment. This cultural transition has made it difficult for humans to recognize their dependence on undomesticated living things on the planet. Biologists recognize the human species is embedded in ecosystems and is dependent on them, just as every other species on the planet is dependent. Technology smoothes out the extremes of existence, but ultimately the human species cannot exist without its ecosystem.

## Human Health

Contemporary societies that live close to the land often have a broad knowledge of the medicinal uses of plants growing in their area. Most plants produce **secondary plant compounds**, which are toxins used to protect the plant from insects and other animals that eat them, but some of which also work as medication. For centuries in Europe, older knowledge about the medical uses of plants was compiled in herbals—books that identified plants and their uses. Humans are not the only species to use plants for medicinal reasons: the great apes, orangutans, chimpanzees, bonobos, and gorillas have all been observed self-medicating with plants.

Modern pharmaceutical science also recognizes the importance of these plant compounds. Examples of significant medicines derived from plant compounds include aspirin, codeine, digoxin, atropine, and vincristine (**Figure 38.8**). Many medicines were once derived from plant extracts but are now synthesized. It is estimated that, at one time, 25 percent of modern drugs contained at least one plant extract. That number has probably decreased to about 10 percent as natural plant ingredients are replaced by synthetic versions. Antibiotics, which are responsible for extraordinary improvements in health and lifespans in developed countries, are compounds largely derived from fungi and bacteria.

**Figure 38.8** *Catharanthus roseus*, the Madagascar periwinkle, has various medicinal properties. Among other uses, it is a source of vincristine, a drug used in the treatment of lymphomas. (credit: Forest and Kim Starr)

In recent years, animal venoms and poisons have excited intense research for their medicinal potential. By 2007, the FDA had approved five drugs based on animal toxins to treat diseases such as hypertension, chronic pain, and diabetes. Another five drugs are undergoing clinical trials, and at least six drugs are being used in other countries. Other toxins under investigation come from mammals, snakes, lizards, various amphibians, fish, snails, octopuses, and scorpions.

Aside from representing billions of dollars in profits, these medicines improve people's lives. Pharmaceutical companies are actively looking for new compounds synthesized by living organisms that can function as medicine. It is estimated that 1/3 of pharmaceutical research and development is spent on natural compounds and that about 35 percent of new drugs brought to market between 1981 and 2002 were from natural compounds. The opportunities for new medications will be reduced in direct proportion to the disappearance of species.

## Agricultural Diversity

Since the beginning of human agriculture more than 10,000 years ago, human groups have been breeding and selecting crop varieties. This crop diversity matched the cultural diversity of highly subdivided populations of humans. For example, potatoes were domesticated beginning around 7,000 years ago in the central Andes of Peru and Bolivia. The potatoes grown in that region belong to seven species and the number of varieties likely is in the thousands. Each variety has been bred to thrive at particular elevations and soil and climate conditions. The diversity is driven by the diverse demands of the topography, the limited movement of people, and the demands created by crop rotation for different varieties that will do well in different fields.

Potatoes are only one example of human-generated diversity. Every plant, animal, and fungus that has been cultivated by humans has been bred from original wild ancestor species into diverse varieties arising from the demands for food value, adaptation to growing conditions, and resistance to pests. The potato demonstrates a well-known example of the risks of low crop diversity: the tragic Irish potato famine when the single variety grown in Ireland became susceptible to a potato blight, wiping out the crop. The loss of the crop led to famine, death, and mass emigration. Resistance to disease is a chief benefit to maintaining crop biodiversity, and lack of diversity in contemporary crop species carries similar risks. Seed companies, which are the source of most crop varieties in developed countries, must continually breed new varieties to keep up with evolving pest organisms. These same seed companies, however, have participated in the decline of the number of varieties available as they focus on selling fewer varieties in more areas of the world.

The ability to create new crop varieties relies on the diversity of varieties available and the accessibility of wild forms related to the crop plant. These wild forms are often the source of new gene variants that can be bred with existing varieties to create varieties with new attributes. Loss of wild species related to a crop will mean the loss of potential in crop improvement. Maintaining the genetic diversity of wild species related to domesticated species ensures our continued food supply.

Since the 1920s, government agriculture departments have maintained seed banks of crop varieties as a way to maintain crop diversity. This system has flaws because, over time, seed banks are lost through accidents, and there is no way to replace them. In 2008, the Svalbard Global Seed Vault ([Figure 38.9](#)) began storing seeds from around the world as a backup system to the regional seed banks. If a regional seed bank stores varieties in Svalbard, losses can be replaced from Svalbard. The seed vault is located deep into the rock of an arctic island. Conditions within the vault are maintained at ideal temperature and humidity for seed survival, but the deep underground location of the vault in the arctic means that failure of the vault's systems will not compromise the climatic conditions inside the vault.

**visual CONNECTION**

**Figure 38.9** The Svalbard Global Seed Vault is a storage facility for seeds of Earth's diverse crops. (credit: Mari Tefre, Svalbard Global Seed Vault)

The Svalbard Global Seed Vault is located on Spitsbergen island in Norway, which has an arctic climate. Why might an arctic climate be good for seed storage?

- a. Such severe climatic conditions don't let seeds dry out; they retain water and remain viable.
- b. The ground is permanently frozen, so the seeds will be kept at 10°C even if the electricity fails.
- c. Because such a climate extends the dormancy periods of seeds to more than what is normal.
- d. Because the ground is permanently frozen, the seeds will be kept below 0°C even if electricity fails.

Crop success is largely dependent on the quality of the soil. Although some agricultural soils are rendered sterile using controversial cultivation and chemical treatments, most contain a huge diversity of organisms that maintain nutrient cycles—breaking down organic matter into nutrient compounds that crops need for growth. These organisms also maintain soil texture that affects water and oxygen dynamics in the soil that are necessary for plant growth. If farmers had to maintain arable soil using alternate means, the cost of food would be much higher than it is now. These kinds of processes are called ecosystem services. They occur within ecosystems, such as soil ecosystems, as a result of the diverse metabolic activities of the organisms living there, but they provide benefits to human food production, drinking water availability, and breathable air.

Other key ecosystem services related to food production are plant pollination and crop pest control. Over 150 crops in the United States require pollination to produce. One estimate of the benefit of honeybee pollination within the United States is \$1.6 billion per year; other pollinators contribute up to \$6.7 billion more.

Many honeybee populations are managed by apiarists who rent out their hives' services to farmers. Honeybee populations in North America have been suffering large losses caused by a syndrome known as colony collapse disorder, whose cause is unclear. Other pollinators include a diverse array of other bee species and various insects and birds. Loss of these species would make growing crops requiring pollination impossible, increasing dependence on other crops.

Finally, humans compete for their food with crop pests, most of which are insects. Pesticides control these competitors; however, pesticides are costly and lose their effectiveness over time as pest populations adapt. They also lead to collateral damage by killing non-pest species and risking the health of consumers and agricultural workers. Ecologists believe that the bulk of the work in removing pests is actually done by predators and parasites of those pests, but the impact has not been well studied. A review found that in 74 percent of studies that looked for an effect of landscape complexity on natural enemies of pests, the greater the complexity, the greater the effect of pest-suppressing organisms. An experimental study found that introducing multiple enemies of pea aphids (an important alfalfa pest) increased the yield of alfalfa significantly. This study shows the importance of landscape diversity via the question of whether a diversity of pests is more effective at control than one single pest; the results showed this to be the case. Loss of diversity in pest enemies will inevitably make it more difficult and costly to grow food.

## Wild Food Sources

In addition to growing crops and raising animals for food, humans obtain food resources from wild populations, primarily fish populations. For approximately 1 billion people, aquatic resources provide the main source of animal protein. But since 1990, global fish production has declined. Despite considerable effort, few fisheries on the planet are managed for sustainability.

Fishery extinctions rarely lead to complete extinction of the harvested species, but rather to a radical restructuring of the marine ecosystem in which a dominant species is so over-harvested that it becomes a minor player, ecologically. In addition to humans losing the food source, these alterations affect many other species in ways that are difficult or impossible to predict. The collapse of fisheries has dramatic and long-lasting effects on local populations that work in the fishery. In addition, the loss of an inexpensive protein source to populations that cannot afford to replace it will increase the cost of living and limit societies in other ways. In general, the fish taken from fisheries have shifted to smaller species as larger species are fished to extinction. The ultimate outcome could clearly be the loss of aquatic systems as food sources.

View a **brief video** ([http://openstaxcollege.org/l/declining\\_fish](http://openstaxcollege.org/l/declining_fish)) discussing declining fish stocks.

What would be the most effective approach to reversing the damage of overfishing?

- Ban all fishing in the oceans of the world for ten years.
- The damage is irreparable and no measure will reverse the loss.
- Fish only overabundant invasive species.
- Set aside 40% of the world's oceans as no-fishing zones with international cooperation for enforcement.

## Psychological and Moral Value

Finally, it has been argued that humans benefit psychologically from living in a biodiverse world. A chief proponent of this idea is entomologist E. O. Wilson. He argues that human evolutionary history has adapted us to live in a natural environment and that built environments generate stressors that affect human health and well-being. There is considerable research into the psychological regenerative benefits of natural landscapes that suggests the hypothesis may hold some truth. In addition, there is a moral argument that humans have a responsibility to inflict as little harm as possible on other species.

## 38.3 | Threats to Biodiversity

In this section, you will explore the following questions:

- What are significant threats to biodiversity?
- What are the impacts of habitat loss, exotic species, and hunting on biodiversity?
- What are examples of early and predicted effects of climate change on biodiversity?

## Connection for AP<sup>®</sup> Courses

The core threats to biodiversity include human population growth and the unsustainable removal of resources from the environment. The three greatest proximate threats to biodiversity are habitat loss, overharvesting, and introduction of exotic species. A fourth major cause of species extinction—climate change—is becoming increasingly more significant.

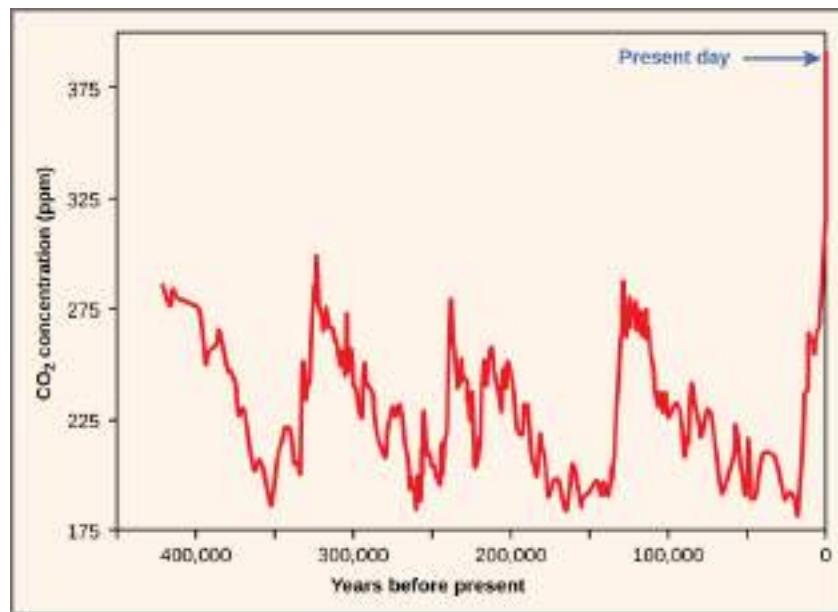

The burning of fossil fuels raises levels of carbon dioxide in the atmosphere, and this “greenhouse effect” results in global climate change.

Information presented and the examples highlighted in the section support concepts outlined in Big Idea 1 and Big Idea 4 of the AP® Biology Curriculum Framework. The AP® Learning Objectives listed in the Curriculum Framework provide a transparent foundation for the AP® Biology course, an inquiry-based laboratory experience, instructional activities, and AP® exam questions. A learning objective merges required content with one or more of the seven science practices.

| <b>Big Idea 1</b>                 | The process of evolution drives the diversity and unity of life.                                                                                                                      |
| <b>Enduring Understanding 1.C</b> | Life continues to evolve within a changing environment.                                                                                                                               |
| <b>Essential Knowledge</b>        | <b>1.C.1</b> Speciation and extinction have occurred throughout Earth's history.                                                                                                      |
| <b>Science Practice</b>           | <b>5.1</b> The student can analyze data to identify patterns or relationships.                                                                                                        |
| <b>Learning Objective</b>         | <b>1.20</b> The student is able to analyze data related to questions of speciation and extinction throughout the Earth's history.                                                     |
| <b>Essential Knowledge</b>        | <b>1.C.1</b> Speciation and extinction have occurred throughout Earth's history.                                                                                                      |
| <b>Science Practice</b>           | <b>4.2</b> The student can design a plan for collecting data to answer a particular scientific question.                                                                              |
| <b>Learning Objective</b>         | <b>1.21</b> The student is able to design a plan for collecting data to investigate the scientific claim that speciation and extinction have occurred throughout the Earth's history. |
| <b>Big Idea 4</b>                 | Biological systems interact, and these systems and their interaction possess complex properties.                                                                                      |
| <b>Enduring Understanding 4.A</b> | Interactions within biological systems lead to complex properties.                                                                                                                    |
| <b>Essential Knowledge</b>        | <b>4.A.6</b> Interactions among living systems and with their environment result in the movement of matter and energy.                                                                |
| <b>Science Practice</b>           | <b>6.4</b> The student can make claims and predictions about natural phenomena based on scientific theories and models.                                                               |
| <b>Learning Objective</b>         | <b>4.16</b> The student is able to predict the effects of a change of matter or energy availability on communities.                                                                   |
| <b>Big Idea 4</b>                 | Biological systems interact, and these systems and their interaction possess complex properties.                                                                                      |
| <b>Enduring Understanding 4.B</b> | Competition and cooperation are important aspects of biological systems.                                                                                                              |
| <b>Essential Knowledge</b>        | <b>4.B.4</b> Distribution of local and global ecosystems changes over time.                                                                                                           |
| <b>Science Practice</b>           | <b>6.4</b> The student can make claims and predictions about natural phenomena based on scientific theories and models.                                                               |
| <b>Learning Objective</b>         | <b>4.21</b> The student is able to predict consequences of human actions on both local and global ecosystems.                                                                         |

The human population requires resources to survive and grow, and those resources are being removed unsustainably from the environment. As mentioned, the three greatest proximate threats to biodiversity are habitat loss, overharvesting, and

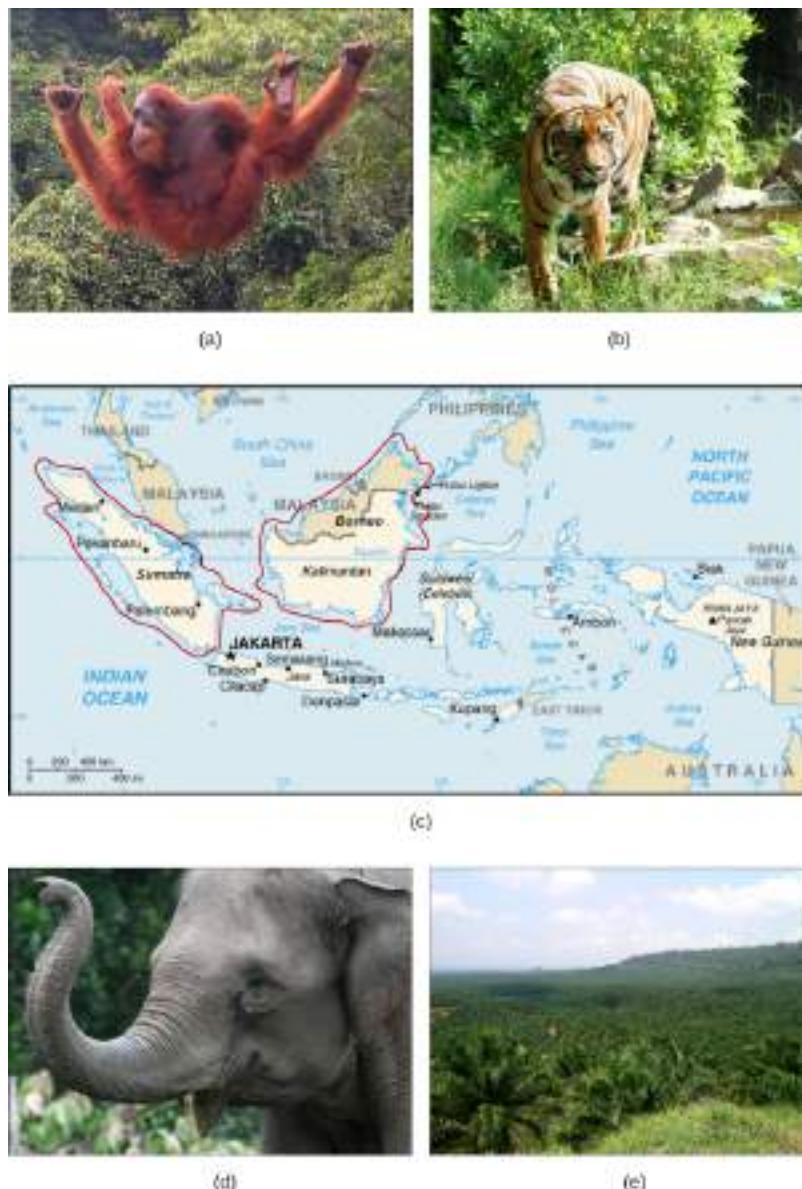

introduction of exotic species. The first two of these are a direct result of human population growth and resource use. The third results from increased mobility and trade. A fourth major cause of extinction, anthropogenic climate change, has not yet had a large impact, but it is predicted to become significant during this century. Global climate change is also a consequence of human population needs for energy and the use of fossil fuels to meet those needs ([Figure 38.10](#)). Environmental issues, such as toxic pollution, have specific targeted effects on species, but they are not generally seen as threats at the magnitude of the others.

**Figure 38.10** Atmospheric carbon dioxide levels fluctuate in a cyclical manner. However, the burning of fossil fuels in recent history has caused a dramatic increase in the levels of carbon dioxide in the Earth's atmosphere, which have now reached levels never before seen in human history. Scientists predict that the addition of this "greenhouse gas" to the atmosphere is resulting in climate change that will significantly impact biodiversity in the coming century.

## Habitat Loss

Humans rely on technology to modify their environment and replace certain functions that were once performed by the natural ecosystem. Other species cannot do this. Elimination of their ecosystem—whether it is a forest, a desert, a grassland, a freshwater estuarine, or a marine environment—will kill the individuals in the species. Remove the entire habitat within the range of a species and, unless they are one of the few species that do well in human-built environments, the species will become extinct. Human destruction of habitats accelerated in the latter half of the twentieth century. Consider the exceptional biodiversity of Sumatra: it is home to one species of orangutan, a species of critically endangered elephant, and the Sumatran tiger, but half of Sumatra's forest is now gone. The neighboring island of Borneo, home to the other species of orangutan, has lost a similar area of forest. Forest loss continues in protected areas of Borneo. The orangutan in Borneo is listed as endangered by the International Union for Conservation of Nature (IUCN), but it is simply the most visible of thousands of species that will not survive the disappearance of the forests of Borneo. The forests are removed for timber and to plant palm oil plantations ([Figure 38.11](#)). Palm oil is used in many products including food products, cosmetics, and biodiesel in Europe. A five-year estimate of global forest cover loss for the years 2000–2005 was 3.1 percent. In the humid tropics where forest loss is primarily from timber extraction, 272,000 km<sup>2</sup> was lost out of a global total of 11,564,000 km<sup>2</sup> (or 2.4 percent). In the tropics, these losses certainly also represent the extinction of species because of high levels of endemism.

**Figure 38.11** (a) One species of orangutan, *Pongo pygmaeus*, is found only in the rainforests of Borneo, and the other species of orangutan (*Pongo abelii*) is found only in the rainforests of Sumatra. These animals are examples of the exceptional biodiversity of (c) the islands of Sumatra and Borneo. Other species include the (b) Sumatran tiger (*Panthera tigris sumatrae*) and the (d) Sumatran elephant (*Elephas maximus sumatranus*), both critically endangered species. Rainforest habitat is being removed to make way for (e) oil palm plantations such as this one in Borneo's Sabah Province. # everyday CONNECTION

## Preventing Habitat Destruction with Wise Wood Choices

Most consumers do not imagine that the home improvement products they buy might be contributing to habitat loss and species extinctions. Yet the market for illegally harvested tropical timber is huge, and the wood products often find themselves in building supply stores in the United States. One estimate is that 10 percent of the imported timber stream in the United States, which is the world's largest consumer of wood products, is potentially illegally logged. In 2006, this amounted to \$3.6 billion in wood products. Most of the illegal products are imported from countries that act as intermediaries and are not the originators of the wood.

How is it possible to determine if a wood product, such as flooring, was harvested sustainably or even legally? The Forest Stewardship Council (FSC) certifies sustainably harvested forest products, therefore, looking for their certification on flooring and other hardwood products is one way to ensure that the wood has not been taken illegally from a tropical forest. Certification applies to specific products, not to a producer; some producers' products may not have certification while other products are certified. While there are other industry-backed certifications other than the FSC, these are unreliable due to lack of independence from the industry. Another approach is to buy domestic wood species. While it would be great if there was a list of legal versus illegal wood products, it is not that simple. Logging and forest management laws vary from country to country; what is illegal in one country may be legal in another. Where and how a product is harvested and whether the forest from which it comes is being maintained sustainably all factor into whether a wood product will be certified by the FSC. It is always a good idea to ask questions about where a wood product came from and how the supplier knows that it was harvested legally.

Which of the following woods was most likely legally harvested?

- a. unknown wood stacked in a corner of the store
- b. bird-eye maple from Vermont with a FSC certificate
- c. teak imported from Thailand
- d. purpleheart wood from the Amazon forest

Habitat destruction can affect ecosystems other than forests. Rivers and streams are important ecosystems and are frequently modified through land development and from damming or water removal. Damming of rivers affects the water flow and access to all parts of a river. Differing flow regimes can reduce or eliminate populations that are adapted to these changes in flow patterns. For example, an estimated 91 percent of river lengths in the United States have been developed: they have modifications like dams, to create energy or store water; levees, to prevent flooding; or dredging or rerouting, to create land that is more suitable for human development. Many fish species in the United States, especially rare species or species with restricted distributions, have seen declines caused by river damming and habitat loss. Research has confirmed that species of amphibians that must carry out parts of their life cycles in both aquatic and terrestrial habitats have a greater chance of suffering population declines and extinction because of the increased likelihood that one of their habitats or access between them will be lost.

## Overharvesting

Overharvesting is a serious threat to many species, but particularly to aquatic species. There are many examples of regulated commercial fisheries monitored by fisheries scientists that have nevertheless collapsed. The western Atlantic cod fishery is the most spectacular recent collapse. While it was a hugely productive fishery for 400 years, the introduction of modern factory trawlers in the 1980s and the pressure on the fishery led to it becoming unsustainable. The causes of fishery collapse are both economic and political in nature. Most fisheries are managed as a common (shared) resource even when the fishing territory lies within a country's territorial waters. Common resources are subject to an economic pressure known as the **tragedy of the commons** in which essentially no fisher has a motivation to exercise restraint in harvesting a fishery when it is not owned by that fisher. The natural outcome of harvests of resources held in common is their overexploitation. While large fisheries are regulated to attempt to avoid this pressure, it still exists in the background. This overexploitation is exacerbated when access to the fishery is open and unregulated and when technology gives fishers the ability to overfish. In a few fisheries, the biological growth of the resource is less than the potential growth of the profits made from fishing if that time and money were invested elsewhere. In these cases—whales are an example—economic forces will always drive toward fishing the population to extinction.

Explore a U.S. Fish & Wildlife Service **interactive map** ([http://openstaxcollege.org/l/habitat\\_map](http://openstaxcollege.org/l/habitat_map)) of critical habitat for endangered and threatened species in the United States. To begin, select “Visit the online mapper.”

For the most part, fishery extinction is not equivalent to biological extinction—the last fish of a species is rarely fished out of the ocean. At the same time, fishery extinction is still harmful to fish species and their ecosystems. There are some instances in which true extinction is a possibility. Whales have slow-growing populations and are at risk of complete extinction through hunting. There are some species of sharks with restricted distributions that are at risk of extinction. The groupers are another population of generally slow-growing fishes that, in the Caribbean, includes a number of species that are at risk of extinction from overfishing.

Coral reefs are extremely diverse marine ecosystems that face peril from several processes. Reefs are home to 1/3 of the world’s marine fish species—about 4,000 species—despite making up only 1 percent of marine habitat. Most home marine aquaria are stocked with wild-caught organisms, not cultured organisms. Although no species is known to have been driven extinct by the pet trade in marine species, there are studies showing that populations of some species have declined in response to harvesting, indicating that the harvest is not sustainable at those levels. There are concerns about the effect of the pet trade on some terrestrial species such as turtles, amphibians, birds, plants, and even the orangutan.

View a **brief video** ([http://openstaxcollege.org/l/ocean\\_matters](http://openstaxcollege.org/l/ocean_matters)) discussing the role of marine ecosystems in supporting human welfare and the decline of ocean ecosystems.

The ocean is home to many organisms. How are some of the smallest species connected to human breathing?

- Phytoplankton release over 50% of the oxygen produced on Earth through chemosynthesis.
- Phytoplankton release over 50% of the carbon dioxide produced on Earth through photosynthesis.
- Phytoplankton release over 20% of the oxygen produced on Earth through photosynthesis.
- Phytoplankton release over 50% of the oxygen produced on Earth through photosynthesis.

**Bush meat** is the generic term used for wild animals killed for food. Hunting is practiced throughout the world, but hunting practices, particularly in equatorial Africa and parts of Asia, are believed to threaten several species with extinction. Traditionally, bush meat in Africa was hunted to feed families directly; however, recent commercialization of the practice now has bush meat available in grocery stores, which has increased harvest rates to the level of unsustainability. Additionally, human population growth has increased the need for protein foods that are not being met from agriculture. Species threatened by the bush meat trade are mostly mammals including many primates living in the Congo basin.

## Exotic Species

**Exotic species** are species that have been intentionally or unintentionally introduced by humans into an ecosystem in which they did not evolve. Such introductions likely occur frequently as natural phenomena. For example, Kudzu (*Pueraria lobata*), which is native to Japan, was introduced in the United States in 1876. It was later planted for soil conservation.

Problematically, it grows too well in the southeastern United States—up to a foot a day. It is now a pest species and covers over 7 million acres in the southeastern United States. If an introduced species is able to survive in its new habitat, that introduction is now reflected in the observed range of the species. Human transportation of people and goods, including the intentional transport of organisms for trade, has dramatically increased the introduction of species into new ecosystems, sometimes at distances that are well beyond the capacity of the species to ever travel itself and outside the range of the species' natural predators.

Most exotic species introductions probably fail because of the low number of individuals introduced or poor adaptation to the ecosystem they enter. Some species, however, possess preadaptations that can make them especially successful in a new ecosystem. These exotic species often undergo dramatic population increases in their new habitat and reset the ecological conditions in the new environment, threatening the species that exist there. For this reason, exotic species are also called invasive species. Exotic species can threaten other species through competition for resources, predation, or disease.

Explore an **interactive global database** ([http://openstaxcollege.org/l/exotic\\_invasive](http://openstaxcollege.org/l/exotic_invasive)) of exotic or invasive species.

How do iguanas propagate themselves and other invasive species?

- a. Iguanas interbreed with invasive species and their offspring continue to breed.
- b. Iguanas consume other exotic animal and seed species.
- c. Iguanas reproduce in urban settings and defecate the seeds of invasive plants.
- d. Iguanas reproduce in settings where other invasive species thrive.

Lakes and islands are particularly vulnerable to extinction threats from introduced species. In Lake Victoria, as mentioned earlier, the intentional introduction of the Nile perch was largely responsible for the extinction of about 200 species of cichlids. The accidental introduction of the brown tree snake via aircraft (Figure 38.12) from the Solomon Islands to Guam in 1950 has led to the extinction of three species of birds and three to five species of reptiles endemic to the island. Several other species are still threatened. The brown tree snake is adept at exploiting human transportation as a means to migrate; one was even found on an aircraft arriving in Corpus Christi, Texas. Constant vigilance on the part of airport, military, and commercial aircraft personnel is required to prevent the snake from moving from Guam to other islands in the Pacific, especially Hawaii. Islands do not make up a large area of land on the globe, but they do contain a disproportionate number of endemic species because of their isolation from mainland ancestors.

**Figure 38.12** The brown tree snake, *Boiga irregularis*, is an exotic species that has caused numerous extinctions on the island of Guam since its accidental introduction in 1950. (credit: NPS)

It now appears that the global decline in amphibian species recognized in the 1990s is, in some part, caused by the fungus *Batrachochytrium dendrobatidis*, which causes the disease **chytridiomycosis** ([Figure 38.13](#)). There is evidence that the fungus is native to Africa and may have been spread throughout the world by transport of a commonly used laboratory and pet species: the African clawed toad (*Xenopus laevis*). It may well be that biologists themselves are responsible for spreading this disease worldwide. The North American bullfrog, *Rana catesbeiana*, which has also been widely introduced as a food animal but which easily escapes captivity, survives most infections of *Batrachochytrium dendrobatidis* and can act as a reservoir for the disease.

**Figure 38.13** This Limosa Harlequin Frog (*Atelopus limosus*), an endangered species from Panama, died from a fungal disease called chytridiomycosis. The red lesions are symptomatic of the disease. (credit: Brian Gratwicke)

Early evidence suggests that another fungal pathogen, *Pseudogymnoascus destructans*, introduced from Europe is responsible for **white-nose syndrome**, which infects cave-hibernating bats in eastern North America and has spread from a point of origin in western New York State ([Figure 38.14](#)). The disease has decimated bat populations and threatens extinction of species already listed as endangered: the Indiana bat, *Myotis sodalis*, and potentially the Virginia big-eared bat, *Corynorhinus townsendii virginianus*. How the fungus was introduced is unclear, but one logical presumption would be that recreational cavers unintentionally brought the fungus on clothes or equipment from Europe.

**Figure 38.14** This little brown bat in Greeley Mine, Vermont, March 26, 2009, was found to have white-nose syndrome.

## everyday CONNECTION for AP<sup>®</sup> Courses

Invasive plants can also destroy native habitats. The Brazilian pepper tree pictured below was brought in to Florida in the 1800s. Now widespread throughout Florida, it produces a dense canopy, creating too much shade for native plant species to thrive.

**Figure 38.15** (credit: Forest Starr & Kim Starr)

Populations of bats in many habitats are declining because of an infection referred to as white-nose syndrome. The pathogen forms mycelia, fuzzy tangles of white filaments, on the nose of the bats. When scraped from the nose of bats and observed under the light microscope, the filaments display cells with a nucleus and cell walls. Which of the following organisms is the most probable cause of the white-nose syndrome of bats?

- a. a bacterium
- b. a fungus
- c. a helminth
- d. a virus

### Activity

**Importing of Exotic Species.** Introducing a non-native species into an established community can have a number of possible effects. Using your local environment for inspiration, predict some of these effects. What factors should be considered before the importation of non-native or invasive species? Design a campaign that highlights the dangers of importing a specific non-native or invasive species into your local environment.

## Climate Change

Climate change, and specifically the anthropogenic (meaning, caused by humans) warming trend presently underway, is recognized as a major extinction threat, particularly when combined with other threats such as habitat loss. Scientists disagree about the likely magnitude of the effects, with extinction rate estimates ranging from 15 percent to 40 percent of species committed to extinction by 2050. Scientists do agree, however, that climate change will alter regional climates, including rainfall and snowfall patterns, making habitats less hospitable to the species living in them. The warming trend will shift colder climates toward the north and south poles, forcing species to move with their adapted climate norms

while facing habitat gaps along the way. The shifting ranges will impose new competitive regimes on species as they find themselves in contact with other species not present in their historic range. One such unexpected species contact is between polar bears and grizzly bears. Previously, these two species had separate ranges. Now, their ranges are overlapping and there are documented cases of these two species mating and producing viable offspring. Changing climates also throw off species' delicate timing adaptations to seasonal food resources and breeding times. Many contemporary mismatches to shifts in resource availability and timing have already been documented.

**Figure 38.16** Since 2008, grizzly bears (*Ursus arctos horribilis*) have been spotted farther north than their historic range, a possible consequence of climate change. As a result, grizzly bear habitat now overlaps polar bear (*Ursus maritimus*) habitat. The two kinds of bears, which are capable of mating and producing viable offspring, are considered separate species as historically they lived in different habitats and never met. However, in 2006 a hunter shot a wild grizzly-polar bear hybrid known as a grolar bear, the first wild hybrid ever found.

Range shifts are already being observed: for example, some European bird species ranges have moved 91 km northward. The same study suggested that the optimal shift based on warming trends was double that distance, suggesting that the populations are not moving quickly enough. Range shifts have also been observed in plants, butterflies, other insects, freshwater fishes, reptiles, and mammals.

Climate gradients will also move up mountains, eventually crowding species higher in altitude and eliminating the habitat for those species adapted to the highest elevations. Some climates will completely disappear. The rate of warming appears to be accelerated in the arctic, which is recognized as a serious threat to polar bear populations that require sea ice to hunt seals during the winter months: seals are the only source of protein available to polar bears. A trend to decreasing sea ice coverage has occurred since observations began in the mid-twentieth century. The rate of decline observed in recent years is far greater than previously predicted by climate models.

Finally, global warming will raise ocean levels due to melt water from glaciers and the greater volume of warmer water. Shorelines will be inundated, reducing island size, which will have an effect on some species, and a number of islands will disappear entirely. Additionally, the gradual melting and subsequent refreezing of the poles, glaciers, and higher elevation mountains—a cycle that has provided freshwater to environments for centuries—will also be jeopardized. This could result in an overabundance of salt water and a shortage of fresh water.

## 38.4 | Preserving Biodiversity

In this section, you will explore the following questions:

- What are examples of new technologies for measuring biodiversity and legislative framework for conservation?
- What are the principles and challenges of conservation preserve design?
- What are examples of the effects of habitat restoration and the roles of zoos in biodiversity conservation

### Connection for AP® Courses

The information in this section does not directly apply to concepts and content required for AP®. However, as a student of biology and traveler through the amazing world of Earth's living organisms, you have learned why it is important to protect ecosystems and preserve species. When we think of saving species through conservation efforts, we typically target endangered animals—despite the fact that most of the world's food supply comes from plants, not animals. The challenges associated with preserving biodiversity must be met with understanding biodiversity itself, changes in human behavior and beliefs, and various preservation strategies.

Modern technologies, such as DNA analysis, allow researchers to catalogue species and track genetic and evolutionary changes. Global legislation has been enacted to protect species. The approach to protect individual species alone is insufficient to address the negative impacts of human activities. More effective and widespread conservative efforts, such as the establishment of wildlife and ecosystem preserves, can be implemented. Preserves are areas of land set aside with varying degrees of protection for the organisms that inhabit them. Habitat restoration is another tool for protecting ecosystems and can improve the biodiversity of degraded ecosystems. Conservation has shown that ecosystems and the species that inhabit them, including *Homo sapiens*, can persist and thrive when we recognize the benefits of preserving Earth's habitats.

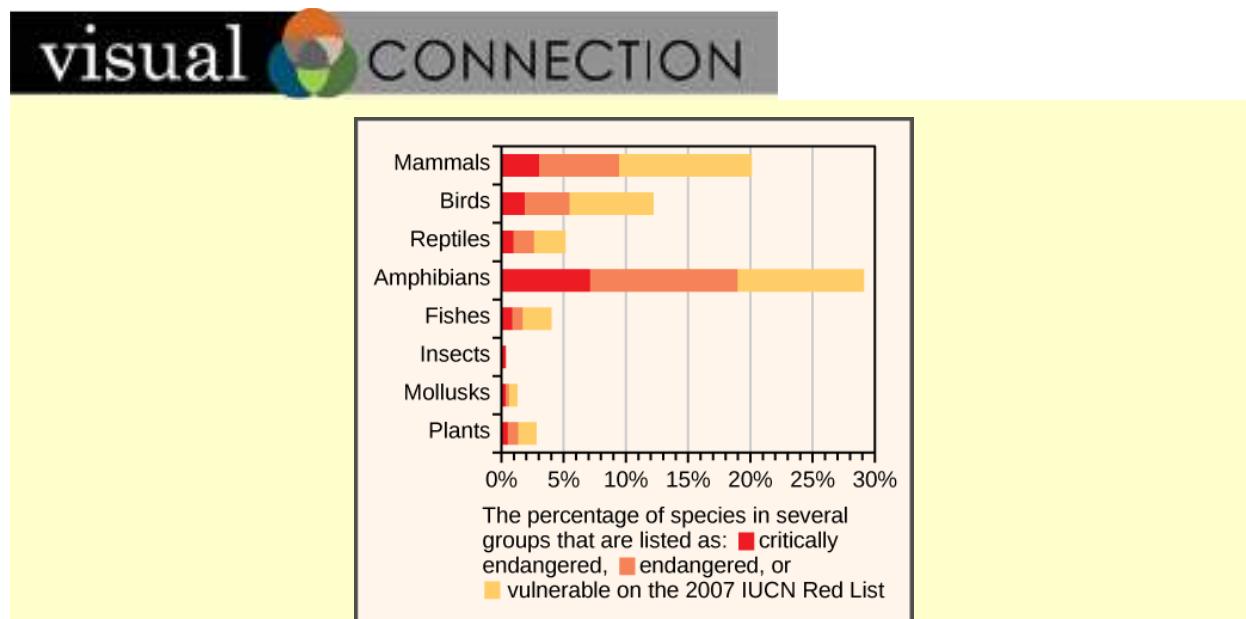

Information presented and examples highlighted in this section are not within the scope for AP® and do not align to the Curriculum Framework.

### Measuring Biodiversity

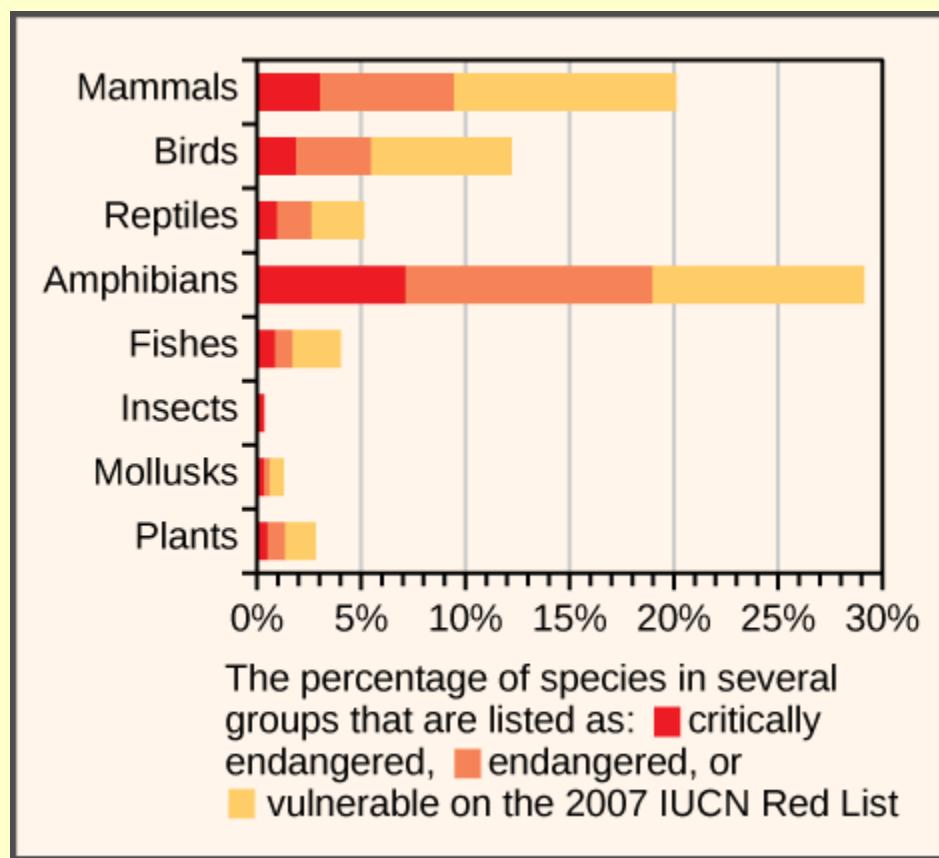

The technology of molecular genetics and data processing and storage are maturing to the point where cataloguing the planet's species in an accessible way is close to feasible. **DNA barcoding** is one molecular genetic method, which takes advantage of rapid evolution in a mitochondrial gene present in eukaryotes, excepting the plants, to identify species using the sequence of portions of the gene. Plants may be barcoded using a combination of chloroplast genes. Rapid mass sequencing machines make the molecular genetics portion of the work relatively inexpensive and quick. Computer resources store and make available the large volumes of data. Projects are currently underway to use DNA barcoding to catalog museum specimens, which have already been named and studied, as well as testing the method on less studied groups. As of mid 2012, close to 150,000 named species had been barcoded. Early studies suggest there are significant numbers of undescribed species that looked too much like sibling species to previously be recognized as different. These now can be identified with DNA barcoding.

Numerous computer databases now provide information about named species and a framework for adding new species. However, as already noted, at the present rate of description of new species, it will take close to 500 years before the complete catalog of life is known. Many, perhaps most, species on the planet do not have that much time.

There is also the problem of understanding which species known to science are threatened and to what degree they are threatened. This task is carried out by the non-profit IUCN which, as previously mentioned, maintains the Red List—an online listing of endangered species categorized by taxonomy, type of threat, and other criteria ([Figure 38.17](#)). The Red List is supported by scientific research. In 2011, the list contained 61,000 species, all with supporting documentation.

**Figure 38.17** This chart shows the percentage of various animal species, by group, on the IUCN Red List as of 2007.

Which of the following statements is not supported by the graph?

- There are more vulnerable fishes than critically endangered and endangered fishes combined.
- There are more critically endangered amphibians than vulnerable, endangered and critically endangered

- reptiles combined.
- c. Within each group, there are more critically endangered species than vulnerable species.
  - d. A greater percentage of bird species are critically endangered than mollusk species.

## Changing Human Behavior

Legislation throughout the world has been enacted to protect species. The legislation includes international treaties as well as national and state laws. The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) treaty came into force in 1975. The treaty, and the national legislation that supports it, provides a legal framework for preventing approximately 33,000 listed species from being transported across nations' borders, thus protecting them from being caught or killed when international trade is involved. The treaty is limited in its reach because it only deals with international movement of organisms or their parts. It is also limited by various countries' ability or willingness to enforce the treaty and supporting legislation. The illegal trade in organisms and their parts is probably a market in the hundreds of millions of dollars. Illegal wildlife trade is monitored by another non-profit: Trade Records Analysis of Flora and Fauna in Commerce (TRAFFIC).

Within many countries there are laws that protect endangered species and regulate hunting and fishing. In the United States, the Endangered Species Act (ESA) was enacted in 1973. Species at risk are listed by the Act; the U.S. Fish & Wildlife Service is required by law to develop management plans that protect the listed species and bring them back to sustainable numbers. The Act, and others like it in other countries, is a useful tool, but it suffers because it is often difficult to get a species listed, or to get an effective management plan in place once it is listed. Additionally, species may be controversially taken off the list without necessarily having had a change in their situation. More fundamentally, the approach to protecting individual species rather than entire ecosystems is both inefficient and focuses efforts on a few highly visible and often charismatic species, perhaps at the expense of other species that go unprotected. At the same time, the Act has a critical habitat provision outlined in the recovery mechanism that may benefit species other than the one targeted for management.

The Migratory Bird Treaty Act (MBTA) is an agreement between the United States and Canada that was signed into law in 1918 in response to declines in North American bird species caused by hunting. The Act now lists over 800 protected species. It makes it illegal to disturb or kill the protected species or distribute their parts (much of the hunting of birds in the past was for their feathers).

The international response to global warming has been mixed. The Kyoto Protocol, an international agreement that came out of the United Nations Framework Convention on Climate Change that committed countries to reducing greenhouse gas emissions by 2012, was ratified by some countries, but spurned by others. Two important countries in terms of their potential impact that did not ratify the Kyoto Protocol were the United States and China. The United States rejected it as a result of a powerful fossil fuel industry and China because of a concern it would stifle the nation's growth. Some goals for reduction in greenhouse gasses were met and exceeded by individual countries, but worldwide, the effort to limit greenhouse gas production is not succeeding. The intended replacement for the Kyoto Protocol has not materialized because governments cannot agree on timelines and benchmarks. Meanwhile, climate scientists predict the resulting costs to human societies and biodiversity will be high.

As already mentioned, the private non-profit sector plays a large role in the conservation effort both in North America and around the world. The approaches range from species-specific organizations to the broadly focused IUCN and TRAFFIC. The Nature Conservancy takes a novel approach. It purchases land and protects it in an attempt to set up preserves for ecosystems. Ultimately, human behavior will change when human values change. At present, the growing urbanization of the human population is a force that poses challenges to the valuing of biodiversity.

## Conservation in Preserves

Establishment of wildlife and ecosystem preserves is one of the key tools in conservation efforts. A preserve is an area of land set aside with varying degrees of protection for the organisms that exist within the boundaries of the preserve. Preserves can be effective in the short term for protecting both species and ecosystems, but they face challenges that scientists are still exploring to strengthen their viability as long-term solutions.

### How Much Area to Preserve?

Due to the way protected lands are allocated (they tend to contain less economically valuable resources rather than being set aside specifically for the species or ecosystems at risk) and the way biodiversity is distributed, determining a target percentage of land or marine habitat that should be protected to maintain biodiversity levels is challenging. The IUCN World Parks Congress estimated that 11.5 percent of Earth's land surface was covered by preserves of various kinds in 2003. This area is greater than previous goals; however, it only represents 9 out of 14 recognized major biomes. Research has shown

that 12 percent of all species live only outside preserves; these percentages are much higher when only threatened species and high quality preserves are considered. For example, high quality preserves include only about 50 percent of threatened amphibian species. The conclusion must be that either the percentage of area protected must increase, or the percentage of high quality preserves must increase, or preserves must be targeted with greater attention to biodiversity protection. Researchers argue that more attention to the latter solution is required.

### **Preserve Design**

There has been extensive research into optimal preserve designs for maintaining biodiversity. The fundamental principle behind much of the research has been the seminal theoretical work of Robert H. MacArthur and Edward O. Wilson published in 1967 on island biogeography.<sup>5</sup> This work sought to understand the factors affecting biodiversity on islands. The fundamental conclusion was that biodiversity on an island was a function of the origin of species through migration, speciation, and extinction on that island. Islands farther from a mainland are harder to get to, so migration is lower and the equilibrium number of species is lower. Within island populations, evidence suggests that the number of species gradually increases to a level similar to the numbers on the mainland from which the species is suspected to have migrated. In addition, smaller islands are harder to find, so their immigration rates for new species are lower. Smaller islands are also less geographically diverse so there are fewer niches to promote speciation. And finally, smaller islands support smaller populations, so the probability of extinction is higher.

As islands get larger, the number of species accelerates, although the effect of island area on species numbers is not a direct correlation. Conservation preserves can be seen as “islands” of habitat within “an ocean” of non-habitat. For a species to persist in a preserve, the preserve must be large enough. The critical size depends, in part, on the home range that is characteristic of the species. A preserve for wolves, which range hundreds of kilometers, must be much larger than a preserve for butterflies, which might range within ten kilometers during its lifetime. But larger preserves have more core area of optimal habitat for individual species, they have more niches to support more species, and they attract more species because they can be found and reached more easily.

Preserves perform better when there are buffer zones around them of suboptimal habitat. The buffer allows organisms to exit the boundaries of the preserve without immediate negative consequences from predation or lack of resources. One large preserve is better than the same area of several smaller preserves because there is more core habitat unaffected by edges. For this same reason, preserves in the shape of a square or circle will be better than a preserve with many thin “arms.” If preserves must be smaller, then providing wildlife corridors between them so that individuals and their genes can move between the preserves, for example along rivers and streams, will make the smaller preserves behave more like a large one. All of these factors are taken into consideration when planning the nature of a preserve before the land is set aside.

In addition to the physical, biological, and ecological specifications of a preserve, there are a variety of policy, legislative, and enforcement specifications related to uses of the preserve for functions other than protection of species. These can include anything from timber extraction, mineral extraction, regulated hunting, human habitation, and nondestructive human recreation. Many of these policy decisions are made based on political pressures rather than conservation considerations. In some cases, wildlife protection policies have been so strict that subsistence-living indigenous populations have been forced from ancestral lands that fell within a preserve. In other cases, even if a preserve is designed to protect wildlife, if the protections are not or cannot be enforced, the preserve status will have little meaning in the face of illegal poaching and timber extraction. This is a widespread problem with preserves in areas of the tropics.

### **Limitations on Preserves**

Some of the limitations on preserves as conservation tools are evident from the discussion of preserve design. Political and economic pressures typically make preserves smaller, never larger, so setting aside areas that are large enough is difficult. If the area set aside is sufficiently large, there may not be sufficient area to create a buffer around the preserve. In this case, an area on the outer edges of the preserve inevitably becomes a riskier suboptimal habitat for the species in the preserve. Enforcement of protections is also a significant issue in countries without the resources or political will to prevent poaching and illegal resource extraction.

Climate change will create inevitable problems with the location of preserves. The species within them will migrate to higher latitudes as the habitat of the preserve becomes less favorable. Scientists are planning for the effects of global warming on future preserves and striving to predict the need for new preserves to accommodate anticipated changes to habitats; however, the end effectiveness is tenuous since these efforts are prediction based.

Finally, an argument can be made that conservation preserves reinforce the cultural perception that humans are separate from nature, can exist outside of it, and can only operate in ways that do damage to biodiversity. Creating preserves reduces the pressure on human activities outside the preserves to be sustainable and non-damaging to biodiversity. Ultimately, the political, economic, and human demographic pressures will degrade and reduce the size of conservation preserves if the activities outside them are not altered to be less damaging to biodiversity.

An **interactive global data system** ([http://openstaxcollege.org/l/protected\\_areas](http://openstaxcollege.org/l/protected_areas)) of protected areas can be found at website. Review data about individual protected areas by location or study statistics on protected areas by country or region.

Access the website in this link and answer the following question. Which country has the largest percentage of its land protected?

- a. Costa Rica
- b. Madagascar
- c. United States
- d. Germany

### **Habitat Restoration**

Habitat restoration holds considerable promise as a mechanism for restoring and maintaining biodiversity. Of course once a species has become extinct, its restoration is impossible. However, restoration can improve the biodiversity of degraded ecosystems. Reintroducing wolves, a top predator, to Yellowstone National Park in 1995 led to dramatic changes in the ecosystem that increased biodiversity. The wolves (**Figure 38.18**) function to suppress elk and coyote populations and provide more abundant resources to the guild of carrion eaters. Reducing elk populations has allowed revegetation of riparian areas, which has increased the diversity of species in that habitat. Decreasing the coyote population has increased the populations of species that were previously suppressed by this predator. The number of species of carrion eaters has increased because of the predatory activities of the wolves. In this habitat, the wolf is a keystone species, meaning a species that is instrumental in maintaining diversity in an ecosystem. Removing a keystone species from an ecological community may cause a collapse in diversity. The results from the Yellowstone experiment suggest that restoring a keystone species can have the effect of restoring biodiversity in the community. Ecologists have argued for the identification of keystone species where possible and for focusing protection efforts on those species; likewise, it also makes sense to attempt to return them to their ecosystem if they have been removed.

**Figure 38.18** (a) The Gibbon wolf pack in Yellowstone National Park, March 1, 2007, represents a keystone species. The reintroduction of wolves into Yellowstone National Park in 1995 led to a change in the grazing behavior of (b) elk. To avoid predation, the elk no longer grazed exposed stream and riverbeds, such as (c) the Lamar Riverbed in Yellowstone. This allowed willow and cottonwood seedlings to grow. The seedlings decreased erosion and provided shading to the creek, which improved fish habitat. A new colony of (d) beaver may also have benefited from the habitat change. (credit a: modification of work by Doug Smith, NPS; credit c: modification of work by Jim Peaco, NPS; credit d: modification of work by "Shiny Things"/Flickr)

Other large-scale restoration experiments underway involve dam removal. In the United States, since the mid-1980s, many aging dams are being considered for removal rather than replacement because of shifting beliefs about the ecological value of free-flowing rivers and because many dams no longer provide the benefit and functions that they did when they were first built. The measured benefits of dam removal include restoration of naturally fluctuating water levels (the purpose of dams is frequently to reduce variation in river flows), which leads to increased fish diversity and improved water quality. In the Pacific Northwest, dam removal projects are expected to increase populations of salmon, which is considered a keystone species because it transports key nutrients to inland ecosystems during its annual spawning migrations. In other regions such as the Atlantic coast, dam removal has allowed the return of spawning anadromous fish species (species that are born in fresh water, live most of their lives in salt water, and return to fresh water to spawn). Some of the largest dam removal projects have yet to occur or have happened too recently for the consequences to be measured. The large-scale ecological experiments that these removal projects constitute will provide valuable data for other dam projects slated either for removal or construction.

#### ***The Role of Captive Breeding***

Zoos have sought to play a role in conservation efforts both through captive breeding programs and education. The transformation of the missions of zoos from collection and exhibition facilities to organizations that are dedicated to conservation is ongoing. In general, it has been recognized that, except in some specific targeted cases, captive breeding programs for endangered species are inefficient and often prone to failure when the species are reintroduced to the wild. Zoo facilities are far too limited to contemplate captive breeding programs for the numbers of species that are now at risk. Education is another potential positive impact of zoos on conservation efforts, particularly given the global trend to urbanization and the consequent reduction in contacts between people and wildlife. A number of studies have been performed to look at the effectiveness of zoos on people's attitudes and actions regarding conservation; at present, the results tend to be mixed.

## KEY TERMS

**adaptive radiation** rapid branching through speciation of a phylogenetic tree into many closely related species

**biodiversity** variety of a biological system, typically conceived as the number of species, but also applying to genes, biochemistry, and ecosystems

**biodiversity hotspot** concept originated by Norman Myers to describe a geographical region with a large number of endemic species and a large percentage of degraded habitat

**bush meat** wild-caught animal used as food (typically mammals, birds, and reptiles); usually referring to hunting in the tropics of sub-Saharan Africa, Asia, and the Americas

**chemical diversity** variety of metabolic compounds in an ecosystem

**chytridiomycosis** disease of amphibians caused by the fungus *Batrachochytrium dendrobatidis*; thought to be a major cause of the global amphibian decline

**DNA barcoding** molecular genetic method for identifying a unique genetic sequence to associate with a species

**ecosystem diversity** variety of ecosystems

**endemic species** species native to one place

**exotic species** (also, invasive species) species that has been introduced to an ecosystem in which it did not evolve

**extinction** disappearance of a species from Earth; local extinction is the disappearance of a species from a region

**extinction rate** number of species becoming extinct over time, sometimes defined as extinctions per million species-years to make numbers manageable (E/MSY)

**genetic diversity** variety of genes in a species or other taxonomic group or ecosystem, the term can refer to allelic diversity or genome-wide diversity

**heterogeneity** number of ecological niches

**megafauna** large animals

**secondary plant compound** compound produced as byproducts of plant metabolic processes that is usually toxic, but is sequestered by the plant to defend against herbivores

**species-area relationship** relationship between area surveyed and number of species encountered; typically measured by incrementally increasing the area of a survey and determining the cumulative numbers of species

**tragedy of the commons** economic principle that resources held in common will inevitably be overexploited

**white-nose syndrome** disease of cave-hibernating bats in the eastern United States and Canada associated with the fungus *Pseudogymnoascus destructans*

## CHAPTER SUMMARY

### 38.1 The Biodiversity Crisis

Biodiversity exists at multiple levels of organization and is measured in different ways depending on the goals of those taking the measurements. These measurements include numbers of species, genetic diversity, chemical diversity, and ecosystem diversity. The number of described species is estimated to be 1.5 million with about 17,000 new species being described each year. Estimates for the total number of species on Earth vary but are on the order of 10 million.

Biodiversity is negatively correlated with latitude for most taxa, meaning that biodiversity is higher in the tropics. The mechanism for this pattern is not known with certainty, but several plausible hypotheses have been advanced.

Five mass extinctions with losses of more than 50 percent of extant species are observable in the fossil record. Biodiversity recovery times after mass extinctions vary, but have been up to 30 million years. Recent extinctions are recorded in written history and are the basis for one method of estimating contemporary extinction rates. The other method

uses measures of habitat loss and species-area relationships. Estimates of contemporary extinction rates vary, but some rates are as high as 500 times the background rate, as determined from the fossil record, and are predicted to rise.

### 38.2 The Importance of Biodiversity to Human Life

Humans use many compounds that were first discovered or derived from living organisms as medicines: secondary plant compounds, animal toxins, and antibiotics produced by bacteria and fungi. More medicines are expected to be discovered in nature. Loss of biodiversity will impact the number of pharmaceuticals available to humans.

Crop diversity is a requirement for food security, and it is being lost. The loss of wild relatives to crops also threatens breeders' abilities to create new varieties. Ecosystems provide ecosystem services that support human agriculture: pollination, nutrient cycling, pest control, and soil development and maintenance. Loss of biodiversity threatens these ecosystem services and risks making food production more expensive or impossible. Wild food sources are mainly aquatic, but few are being managed for sustainability. Fisheries' ability to provide protein to human populations is threatened when extinction occurs.

Biodiversity may provide important psychological benefits to humans. Additionally, there are moral arguments for the maintenance of biodiversity.

### 38.3 Threats to Biodiversity

The core threats to biodiversity are human population growth and unsustainable resource use. To date, the most significant causes of extinctions are habitat loss, introduction of exotic species, and overharvesting. Climate change is predicted to be a significant cause of extinctions in the coming century. Habitat loss occurs through deforestation, damming of rivers, and other activities. Overharvesting is a threat particularly to aquatic species, while the taking of bush meat in the humid tropics threatens many species in Asia, Africa, and the Americas. Exotic species have been the cause of a number of extinctions and are especially damaging to islands and lakes. Exotic species' introductions are increasing because of the increased mobility of human populations and growing global trade and transportation. Climate change is forcing range changes that may lead to extinction. It is also affecting adaptations to the timing of resource availability that negatively affects species in seasonal environments. The impacts of climate change are greatest in the arctic. Global warming will also raise sea levels, eliminating some islands and reducing the area of all others.

### 38.4 Preserving Biodiversity

New technological methods such as DNA barcoding and information processing and accessibility are facilitating the cataloging of the planet's biodiversity. There is also a legislative framework for biodiversity protection. International treaties such as CITES regulate the transportation of endangered species across international borders. Legislation within individual countries protecting species and agreements on global warming have had limited success; there is at present no international agreement on targets for greenhouse gas emissions. In the United States, the Endangered Species Act protects listed species but is hampered by procedural difficulties and a focus on individual species. The Migratory Bird Act is an agreement between Canada and the United States to protect migratory birds. The non-profit sector is also very active in conservation efforts in a variety of ways.

Conservation preserves are a major tool in biodiversity protection. Presently, 11 percent of Earth's land surface is protected in some way. The science of island biogeography has informed the optimal design of preserves; however, preserves have limitations imposed by political and economic forces. In addition, climate change will limit the effectiveness of preserves in the future. A downside of preserves is that they may lessen the pressure on human societies to function more sustainably outside the preserves.

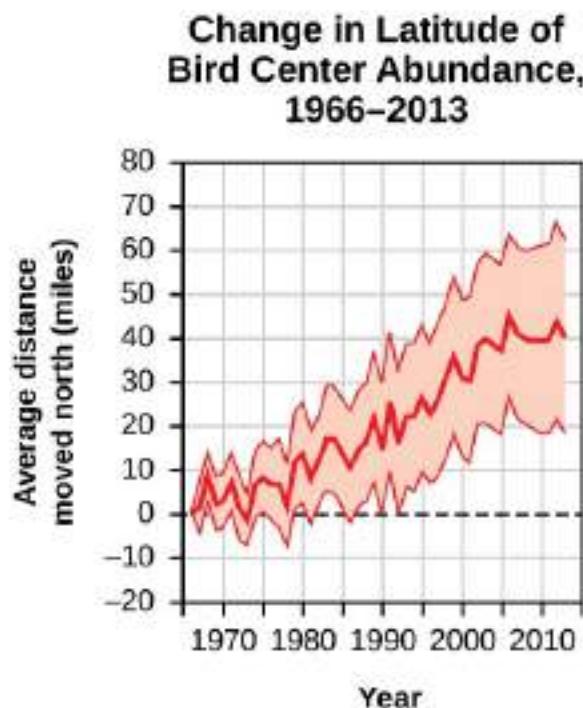

Habitat restoration has the potential to restore ecosystems to previous biodiversity levels before species become extinct. Examples of restoration include reintroduction of keystone species and removal of dams on rivers. Zoos have attempted to take a more active role in conservation and can have a limited role in captive breeding programs. Zoos also may have a useful role in education.

## REVIEW QUESTIONS

1. In an effort to enter all identified species on Earth into a digital catalog, scientists are preparing a unique tag for each species. The following algorithms have been generated to create unique tags. Estimate which algorithm is best suited for the task.

- a. an algorithm that creates 15,000 to 20,000 unique tags
- b. an algorithm that creates 150,000 to 200,000 unique tags
- c. an algorithm that creates 1.5 million to 2 million unique tags
- d. an algorithm that creates 10 million to 20 million unique tags
- 2.** Two genera of birds exist side-by-side on an island. Genus A is characterized by a few species of similar, genetic material. Genus B contains different species of birds with a wide variety of genetic traits. After a volcanic explosion changes the ecosystem, which genus has the highest probability of surviving the disaster?
- Genus A, which contains well adapted species.
  - Genus B, which has greater genetic diversity and is more likely to have traits that confer an advantage in the new environment.
  - Genus A, which can serve as ancestors for the new species.
  - Genus B, because these species likely evolved from Genus A species in the past.
- 3.** A report describes the biodiversity of an island in a remote archipelago in the Pacific Ocean having a larger number of species of birds than neighboring islands. The biologists that investigated the ecosystem of the island described it as an example of adaptive radiation. Their conclusion is based on the fact that they observed \_\_\_\_.
- a burst of speciation
  - the presence of invasive species
  - a hypothesized cause of a mass extinction
  - evidence of an apex predator
- 4.** Findings from layers dating to the Cambrian geological period show an appearance of many new organisms in addition to older forms of life. The Cambrian explosion corresponds to a time where \_\_\_\_.
- New species radiated from existing species.
  - New species appeared due to spontaneous mutations.
  - Ancient species were replaced by newly evolved species.
  - A massive die-out freed ecosystems for new species.
- 5.** Paleontologists are analyzing fossils from a newly excavated site with layers dating from several geological periods. They established a particular layer probably correlates to a mass extinction. Which of the following is the most likely reason for their conclusion?
- a. Over 95 percent of species present in older layers have disappeared in this particular layer.
- b. An asteroid impact altered the geological terrain significantly.
- c. All of the fossils observed were of larger sized organisms.
- d. A loss of over 50 percent of species was observed.
- 6.** What is a likely reason that small animals survived the cataclysmic impact of a large meteorite that caused the massive extinction at the Cretaceous-Paleocene?
- Small animals stopped being hunted by dinosaurs.
  - Small animals do not depend on plants for food.
  - Small animals needed less food for survival and reproduce rapidly.
  - Small animals fed on the dead dinosaurs.
- 7.** Scientists are evaluating an island ecosystem to be upgraded to a hot spot of biodiversity. They conduct field research on the species that populate the area. Their final assessment on the biodiversity of the ecosystem will be based on which estimate?
- the total number of species in an ecosystem
  - the total number of organisms in an ecosystem
  - the total number of species divided by the area of the ecosystem
  - the total number of endangered species in an ecosystem
- 8.** A secondary plant compound might be used for which of the following?
- a new crop variety
  - a new drug
  - a soil nutrient
  - a new species
- 9.** A component of snake venom kills the prey by preventing blood from clotting. Which of the following is the most likely medical application for the active component?
- promoting scab formation
  - speeding healing of wounds
  - relaxing muscle pain
  - a blood thinner
- 10.** Different varieties of potatoes are known to thrive at different altitudes. What could be the related benefit of maintaining the diversity of potato plants?

- a. Diverse types of pollinators can be involved.  
b. The range of usable land is extended.  
c. The taste of potatoes when fried is improved.  
d. Resistance to pests can be introduced if necessary.
- 11.** Which of the following agricultural crops is most likely to survive a catastrophic event?
- monoculture of a crop on a large surface
  - diverse varieties of a crop surrounded by a diverse ecosystem
  - single crop surrounded by a diverse ecosystem
  - diverse varieties of a crop in a simple ecosystem
- 12.** Which factor is present in an ecosystem that performs the same role as a pesticide?
- pollination
  - plant resistance to chemicals
  - asexual reproduction
  - presence of insect predators
- 13.** Urban designers included wetlands and lagoons connected to a water treatment plant to a new subdivision of homes. The designers would have most likely applied which principle of conservation to their plans?
- ecosystem service
  - biodiversity preservation
  - habitat restoration
  - chemical diversity
- 14.** Most antibiotics in use today are prepared or derived from \_\_\_\_.
- secondary compounds from microorganisms
  - secondary compounds from viruses
  - fully synthetic chemical compounds
  - compounds synthesized by plants
- 15.** Loss of biodiversity and accelerations of extinction rates have several causes. Which of the following situations causes direct loss of biodiversity owing to loss of habitat?
- fishing cod at a rate that is greater than natural replacement
  - converting a prairie to a farm field
  - introduction of an invasive ornamental plant in a new ecosystem
  - emission of greenhouse gases increasing the average temperatures of an area
- 16.** Which of the following activities will result in major habitat loss?
- a. picking wild flowers in a meadow  
b. cutting a tree in one's backyard  
c. a farmer switching from wheat to soy crop  
d. building a dam that will flood a large plain
- 17.** Exotic predator species are especially threatening to what kind of ecosystem?
- deserts
  - marine ecosystems
  - islands
  - tropical forests
- 18.** Backpackers returning from a long trip abroad are stopped by customs and asked whether they brought back plants, flowers or fruit from their trip location. Their fruit bought at a local market is confiscated. Why was the fruit confiscated?
- The hikers are supposed to pay duty on imported fruit.
  - The fruit can be processed to produce illicit drugs.
  - The fruit seed could be planted and could eliminate all local species.
  - The fruit may introduce new exotic pests that threaten local plants.
- 19.** Grizzly bears and black bears have a varied diet and hunting grounds. On the other hand, polar bears feed mostly on seals. They walk on the sea ice and wait by breathing holes for seals to emerge from the water for fresh air. Which of the following animals would be most affected by the melting of sea ice in Alaska?
- grizzly bears
  - polar bears
  - koalas
  - black bears
- 20.**

This graph shows the movement northward of wintering grounds of North American bird species. The trend closely mirrors the increase in average winter temperatures. What is one problem that could develop from birds using farther north areas?

- a. Abandoned wintering grounds are left with a poorer ecosystem.
  - b. Movement northward leads to overcrowding of reproductive grounds.
  - c. Food competition increases with birds that do not migrate.
  - d. All of the above.
21. The method of DNA barcoding allows cataloguing of an organism using rapid sequencing methods. The choice of which gene to use for barcoding is guided by its rate of evolution. Which genes are most useful for barcoding eukaryotes with the exception of plants?
- a. nuclear genes
  - b. chloroplast genes
  - c. plasmids
  - d. mitochondrial
22. The choice of using a mitochondrial gene for barcoding of genes depends on \_\_\_\_\_.
- a. the fact that suitable primers for sequencing are not available for nuclear genes
  - b. Any gene can be used.
  - c. the slow rate of evolution in mitochondrial genes
  - d. that there is less variability between individuals of a same species than between individuals of different species
23. While planning an ecological preserve, conservationists plan for an area limited in size with highly diversified niches, which provide habitats to a rich diversity of species. With these constraints in mind, decide which of the following ecosystems is the foundation of the preserve design?
- a. desert
  - b. islands
  - c. the tropical rain forest
  - d. the temperate rain forest
24. A marine preserve is designed off the coast of the Northwest of the US. The coast is dotted by several Native American reservations where the traditional occupation is catching and processing fish. Which parties must be involved in the design of the preserve?
- a. marine biologists only
  - b. marine biologists and oceanographers
  - c. marine biologists, oceanographers, and policy makers
  - d. marine biologists, oceanographers, policy makers, and representatives of the tribes
25. Loss of wetlands has a great impact both on the biotic and abiotic parts of an ecosystem. Wetlands provide rich habitats and act as a filter for pollution. Some loss of wetland is due to silt and invasive species clogging water flow. To restore these wetlands, it is often enough to \_\_\_\_\_.
- a. Open new waterways.
  - b. Restore the water supply.
  - c. Re-introduce endangered animals.
  - d. Introduce water adapted plants.
26. Acid mining pollutes nearby streams by acidifying water and discharging highly toxic by-products. Bacteria have been used to neutralize the pH and detoxify chemical compounds making the stream suitable for animals and plants. This approach to restoration of habitat is an example of \_\_\_\_\_.
- a. keystone species introduction
  - b. bioremediation
  - c. ecosystem preservation
  - d. biological control
27. What was the name of the first international agreement

on climate change?

- a. Red List
- b. Montreal Protocol
- c. International Union for the Conservation of Nature (IUCN)
- d. Kyoto Protocol

## CRITICAL THINKING QUESTIONS

**28.** Which factor explains that in general, temperate and polar regions have less biodiversity than tropical regions?

- a. The tropical regions are subjected to extreme changes of season.
- b. The polar regions were populated earliest in the history of Earth.
- c. The polar regions receive more intense solar energy.
- d. The tropical regions contain more micro-ecosystems.

**29.** One method used to calculate contemporary extinction rates is based on the recorded extinction of species in the last 500 years. A second method is a calculation based on the rate of habitat destruction. The construction of a new dam is being projected. A team of conservation biologists is preparing a report on the environmental impact of the dam. Decide which of the two methods should be adopted to estimate the effect of the construction of the extinction rate in the area and analyze the advantages and disadvantages of each method.

- a. The extinction rates calculation method should be adopted. It is based on a large number of observations and measurements but overestimates rates of extinction. The rate of habitat destruction calculation method uses species-area curves, but underestimates the rate of extinction.
- b. The extinction rates calculation method should be adopted. It is based on a large number of observations and measurements, but overestimates rates of extinction. The rate of habitat destruction calculation method uses species-area curves, but underestimates the rate of extinction.
- c. The rate of habitat destruction calculation method should be adopted. The extinction rates calculation method is based on a large number of observations and measurements but overestimates rates of extinction. The rate of habitat destruction calculation method uses species-area curves, but underestimates the rate of extinction.
- d. Extinction rates are calculated based on the recorded extinction of species in the past 500 years using data from a large number of observations and measurements. They do not take into account unobserved extinctions and undiscovered species. In this way, the method underestimates rates of extinction. The second method based on the amount of habitat destruction and on species-area curves is more adapted to this situation, although it is not based on existing data and is likely to overestimate the rate of extinction.

**30.** Analyze the evidence scientists provide for the cause of the Cretaceous–Paleogene mass extinction.

- a. the unusual abundance of iridium in the Cretaceous-Paleogene layers, the disappearance of so many species at its transition, volcanic activity that led to global warming, and the crater found in the Yucatan peninsula
- b. the unusual abundance of iridium in the Cretaceous-Paleogene layers, gamma-ray burst caused by a nearby supernova, rocks found in the clay layer at its boundary, and the crater found in the Yucatan peninsula
- c. the unusual abundance of iridium in the Cretaceous-Paleogene layers, the disappearance of so many species at its transition, rocks found in the clay layer at its boundary, asteroid impact, and volcanic eruptions at large
- d. the unusual abundance of iridium in the Cretaceous-Paleogene layers, the disappearance of so many species at its transition, rocks found in the clay layer at its boundary, and the crater found in the Yucatan peninsula
- 31.** The island of Madagascar is located in the tropics 300 miles east of the coast of Africa, from which it separated 165 million years ago. It is characterized by a large number of endemic species. What are the main reasons that Madagascar is a hotspot of endemic biodiversity?
- Madagascar has a climate that is more conducive to evolution than the larger African continent.
  - Madagascar is close to the tropics of Africa and consequently has a large number of species.
  - Madagascar shows species diversity of both temperate and tropical regions.
  - Madagascar has been isolated geographically and species evolved there without interaction with outside influences.
- 32.** Consider the following examples. The toxicity in the venom from a Brazilian viper (*Bothrops jararaca*) is due to a sudden, massive drop in blood pressure, which slows down the reaction of a bitten prey. Solutions made from the opium poppy have been used in the past to dull the sensation of pain and induces a sense of wellbeing. How can the effects of these natural compounds be applied to the development of medical treatments?
- a. Compounds similar to the snake's active toxin are used routinely as antivirals. Opioids are used as immunomodulators, which modifies an immune response.
- b. Compounds similar to the snake's active toxin are used routinely as painkillers. Opioids help in the lowering of blood pressure.
- c. Compounds similar to the snake's active toxin are used to treat inflammations. Opioids are used to prevent muscle spasms.
- d. Compounds similar to the snake's active toxin are used to lower blood pressure. Opioids are used routinely as painkillers.
- 33.** Phylloxera, a pest related to aphids, destroyed many vineyards in France at the end of the 19th century. The vineyards were restored by grafting old vines on American root stocks, which were resistant to the pest. Using this situation, explain how biodiversity loss can impact crop diversity.
- Loss of wild species would result in inbreeding depression, as crop varieties must be bred with wild species to remain viable.
  - Loss of biodiversity reduces large-scale monocultures but reinforces genetic homogeneity contributing in the loss of crop diversity.
  - Loss of wild species would result in an increase of intraspecific diversity within the different crop varieties, but decrease in interspecific crop diversity.
  - Loss of wild species would reduce the genetic variations as genes from wild relatives are brought into crop varieties to add valued characteristics to crops.
- 34.** Predict the consequences of the bee colony collapse disorder in a state such as California, which is a large supplier of produce.
- Only pharmaceutical manufacturing and industries involved in honey production are going to be affected due to this disorder.
  - Other pollinators would replace the bees in the ecosystem and there would probably not be a major impact on the production of produce.
  - Lack of pollinators would affect the honey industry, but not the fruit harvest industry, because other pollinators are present to carry out pollination.
  - The lack of pollinators will affect the fruit harvest directly, and indirectly affect industries linked to it like the honey and jam preparation industries.
- 35.** Many chemical pesticides can be found in the bark and leaves of tropical plants. What is a difference in tropical

plants that makes it especially beneficial to produce compounds that kill insects throughout the year?

- Because plants have to protect themselves year-round, as cold spells in winter do not kill pests as they do in temperate areas.
- Because the plants must protect themselves from insects as repellants and toxins sprayed by humans do not work in tropical areas.
- Because the compounds produced to kill insects also enhances the ability of the plant to recover from damage caused by various phenomena.
- Because compounds produced to kill insects also influence the behavior and growth of tropical plants.

**36.** Explain how the increase in human population and resource use causes increased extinction rates by altering ecosystems.

- Human population growth leads to unsustainable resource use, habitat destruction, and the unsustainable fishing and hunting of wild animal populations. All these incidences results in a slow evolutionary rate of formation of new species.
- Human population growth leads to unsustainable resource use, habitat destruction, and the unsustainable fishing and hunting of wild animal populations. Climate change also occurs due to excessive use of fossil fuels.
- Human population growth leads to unsustainable resource use, habitat destruction, and unsustainable fishing and hunting of wild animal populations. Excessive use of fossil fuels is leading to reduced populations of fish species.
- Human population growth leads to unsustainable resource use, habitat destruction, and unsustainable fishing and hunting of wild animal populations. Larger human populations are also leading to decreased value of products obtained from species.

**37.** As a conservationist, you are preparing a report on a frog population living on a mountainside in Costa Rica. In your report, which potential threats to the survival of the species will you predict taking into account environmental abiotic conditions and human activities?

- The frog is at risk from climate change, habitat destruction, and aggressive predators.
- The frog is at risk from climate change, exotic species, and possible habitat destruction.
- The frog is at risk from climate change, habitat destruction, and sparse availability of food.
- The frog is at risk from climate change, exotic species, and over-hunting in its habitat.

**38.** Epidemiologists are predicting that diseases such as

West Nile virus infection, dengue fever, and even malaria may expand their range. If the pathogens are viruses or protists, how could they most rapidly expand their range over a large geographic area?

- through the air
- through contaminated food and water
- through direct human contact from increased presence in wilderness areas
- through vectors such as mosquitoes

**39.** Explain why the hunting of large, top predators such as sharks or wolves, endanger the entire ecosystems in which they live.

- The disappearance of top predators results in unrestricted multiplication of producers. Producers will overgraze primary consumers.
- If a top predator disappears, the primary consumers will multiply without restriction, but producers will not be affected.
- If a top predator disappears, producers will multiply without restriction.
- The disappearance of top predators results in unrestricted multiplication of primary consumers. Primary consumers will overgraze producers.

**40.** The Convention on International Trade in Endangered Species (CITES) passed a resolution to protect rhinoceroses in the wild. Rhinoceroses have been hunted to the brink of extinction because their horns, which are made of simple keratin, are considered an aphrodisiac and a powerful drug in some cultures. Why does the protection of rhinoceroses require an international agreement?

- The rhinoceroses are hunted in their native countries, but the trade crosses borders.
- The use of rhinoceros' horns as an aphrodisiac has showed various negative effects internationally.
- The hunters from different countries travel to the native country to hunt for rhinoceroses.
- Their demand is greater in foreign countries as compared to their native countries.

**41.** A preserve design is proposed for a densely populated suburban area. Which overall design plan would be best for preservation of local ecosystems?

- Set up many, small, protected areas.
- Select one, small area that is isolated from residences.
- Plan buffer zones around all backyard spaces.
- Set up several, larger areas to be set aside for natural ecosystems.

**42.** Wolves are a keystone species in the Yellowstone National Park. Predict what would happen if they were

hunted to extinction.

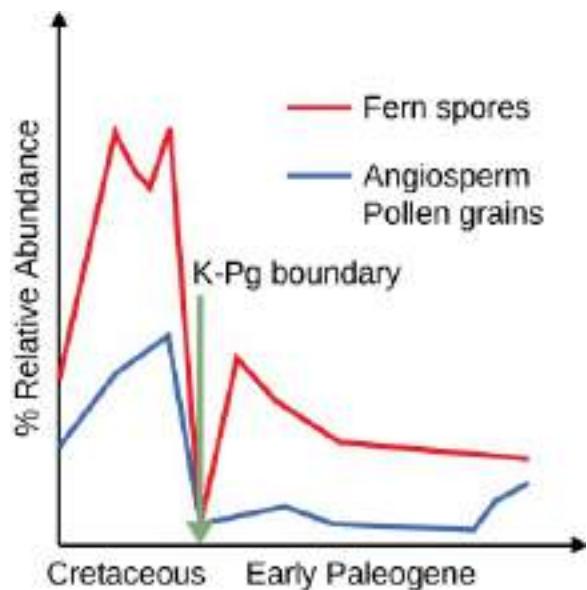

- Many species would increase and the elk population would disappear.
- Many species would disappear and the elk population would increase.
- Many species along with elk population would increase.
- Many species, along with the elk population, would disappear.

**43.** Why have international treaties been rarely enforced so far?

- Signatory nations follow through with their good intentions. No governing body enforces international environmental protection.
- Signatory nations do not follow through with their good intentions. A governing body enforces international environmental protection.
- Signatory nations do not follow through with their good intentions. No governing body enforces international environmental protection.
- Signatory nations follow through with their good intentions. A governing body enforces international environmental protection, but neither is effective.

## TEST PREP FOR AP® COURSES

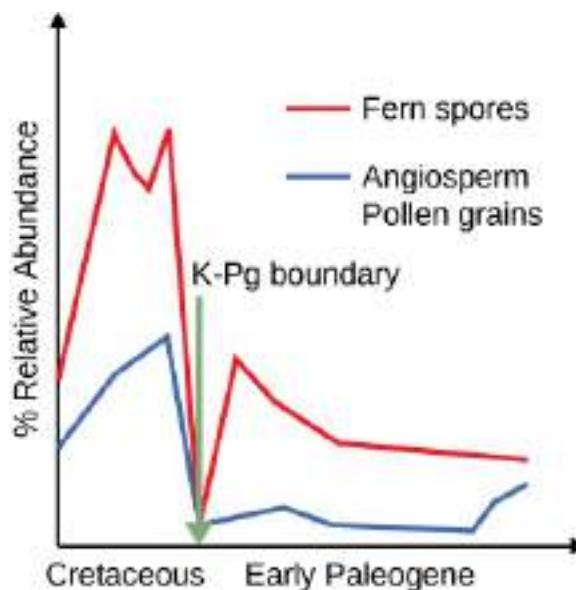

**44.**

Students analyze pollen grains and fern spores recovered from sediments taken below and above the Cretaceous-Paleogene boundary. Their results are summarized in the graph. Which of the following conclusions can be drawn from the graph regarding the impact of the mass extinction that took place at the K-Pg boundary on plants?

- The mass extinction event reduced the number of ferns and angiosperms.
- Based on their reduced pollen counts found in the samples, the mass extinction event clearly reduced the number of ferns and angiosperms.
- The mass extinction affected only the ferns.
- Ferns were more abundant after the Cretaceous-Paleogene (K-Pg) mass extinction than before.

**45.**

Analyze the graph and discuss the reasons for the fern spike seen in the early Paleogene, considering ferns were the first plants seen on the ground after the volcanic eruption of Krakatoa and Mt. St. Helens. Propose reasons for the observed increase in fern spores following the mass extinction.

- a. Ferns are considered early colonizers as they grow fast on poor soil and reproduce rapidly. Also, mass extinction gave an opportunity for the surviving species to expand and radiate to occupy vacated niches.
- b. Ferns, having a selective advantage of being early colonizers, grew fast on poor soil and reproduced rapidly, thus replaced angiosperms in the landscape.
- c. Ferns are considered early colonizers as they grow fast on poor soil and reproduce rapidly. Also, mass extinction gave an opportunity for new species to radiate and thereby occupy vacated niches.
- d. Most of the fern varieties became extinct, only a single species survived; therefore, the remaining fern spores had many vacated niches to occupy which lead to an increase in fern numbers.

46.

| Mass Extinction              | Time of Extinction (millions of years ago) | Organisms Greatly Reduced or Made Extinct                              |
|------------------------------|--------------------------------------------|------------------------------------------------------------------------|
| End of the Ordovician period | 443                                        | Trilobites<br>Brachiopods<br>Echinoderms<br>Corals                     |

A group of students summarized information on five great extinction events. The students are sampling a site in

search of fossils from the Devonian period. Based on the chart, which of the following would be the most reasonable plan for the students to follow?

- a. Searching horizontally rock layers in any class of rock and trying to find those that contain the greatest number of fossils.
- b. Collecting fossils from rock layers deposited prior to the Permian period that contain some early vertebrate bones.
- c. Looking in sedimentary layers next to bodies of water in order to find marine fossils of bivalves and trilobites
- d. Using relative dating techniques to determine the geological ages of the fossils so they can calculate the rate of speciation of early organisms.

47.

|                            | Average Number of Grains/m <sup>2</sup> | Morphology            |
|----------------------------|-----------------------------------------|-----------------------|
| Below Cretaceous-Paleogene | 102                                     | Many different shapes |
| Above Cretaceous-Paleogene | 30                                      | A few common shapes   |

Students are sorting fossils of angiosperm pollen grains, some recovered from layers below the Cretaceous-Paleogene boundary and some from layers above the Cretaceous-Paleogene boundaries. The pollen grains are sorted by morphology.

The results are summarized in a table.

Can you explain the results?

- a. The mass extinction that took place at the Cretaceous-Paleogene boundaries reduced the total number of organisms, seen by fewer shapes of pollen grains, and led to a loss of diversity, seen by the less number.
- b. The mass extinction that took place at the Cretaceous-Paleogene boundaries reduced the total number of organisms, seen by less number of pollen grains, and led to a loss of diversity, seen by fewer shapes.
- c. The mass extinction that took place at the Cretaceous-Paleogene boundaries reduced the total number of organisms, seen by less number of pollen grains.
- d. The mass extinction that took place at the Cretaceous-Paleogene boundaries led to a loss of diversity, seen by fewer shapes of pollen grains.

48.

A dig in a farmland soil rich in calcium carbonate reveals the following findings: 1. Numerous shells of bivalves 2. Chips of corals 3. The partial imprint of a trilobite 4. A

few vertebrae dated to 250 million years ago. The table of extinction summarizes information on the five major extinction events.

According to the table of extinction, which conclusion about the fossils is most reasonable?

- a. The trilobites were the first animals to conquer land.
- b. The rocks can be dated to the Cretaceous-Cretaceous-Paleogene boundary.
- c. The farmland was probably part of the seafloor in the Permian period
- d. The fossils can be dated to the Ordovician period.

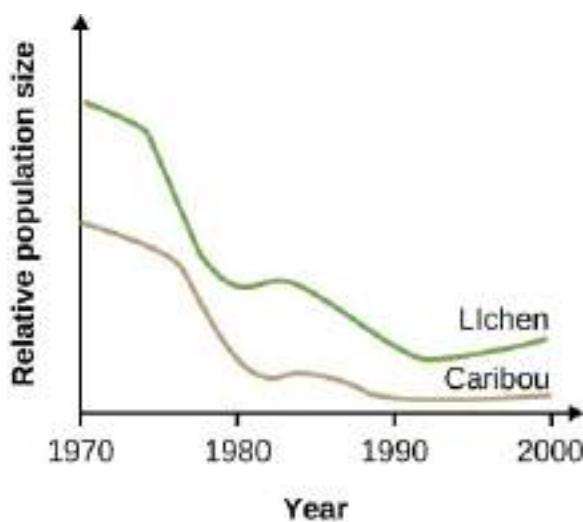

49.

The average temperatures varied during the Pleistocene as glaciation periods were followed by warm intervals. Using the graph above and your existing knowledge, discuss what happened to woolly mammoths and other cold-adapted megafauna 10,000 years ago.

- a. Habitat destruction due to varying temperatures and over-hunting by humans leading to their extinction.
- b. Sudden increase in temperature and over-hunting by humans leading to their extinction.
- c. Gradual increase in temperature and over-hunting by humans leading to their extinction.
- d. Sudden increase in temperature and in predation by larger mammals leading to their extinction.

50.

In winter, lichens are the only food for the caribou herds that roam the tundra. As the average temperatures increase with climate change, the lichen are gradually being replaced by shrubs and trees in the southern parts of the tundra. The graph illustrates the changes in abundance of lichens and caribou over time in a regional forest of Canada. Which statement best explains the changes in the caribou population between 1975 and 1980?

- a. The caribou population expanded after the population of lichens dropped.
- b. The decline of the caribou population and the lichen population are not related.
- c. The population of caribou decreased following the drop in lichen availability.
- d. The caribou population was eliminated once the lichens decreased.

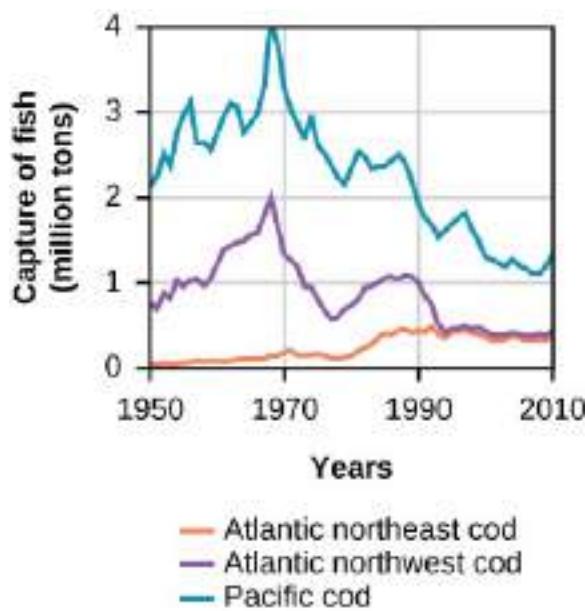

51. A chain within the food web in the arctic ocean is shown below:

Phytoplankton → zooplankton → arctic char/cod → ringed seal → polar bear. A chain within the arctic food web on land is shown below: Lichen/shrub → Caribou/hare/small rodent → fox/lynx/bird of prey

If polar bears move to land to hunt due to loss of sea ice, what will happen to the balance of the food web?

- a. Polar bears, being top predators, will edge out the other consumers without gaining enough calories themselves.
- b. Polar bears, being secondary consumers, will edge out the other consumers without gaining enough calories themselves.
- c. Polar bears, being top predators, will edge out the producers without gaining enough calories themselves.
- d. Polar bears, being secondary consumers, will edge out the producers without gaining enough calories themselves.

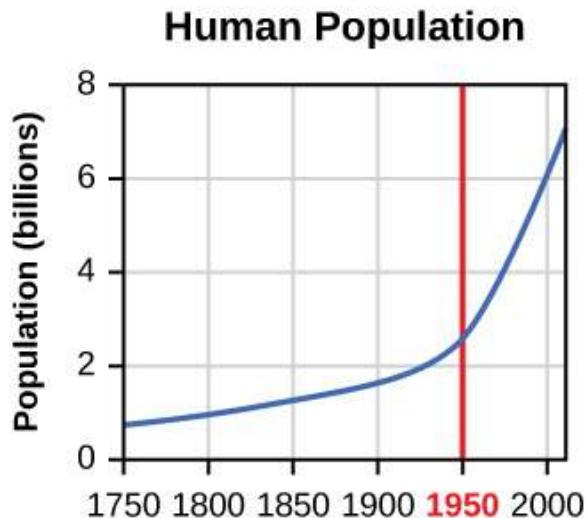

52.

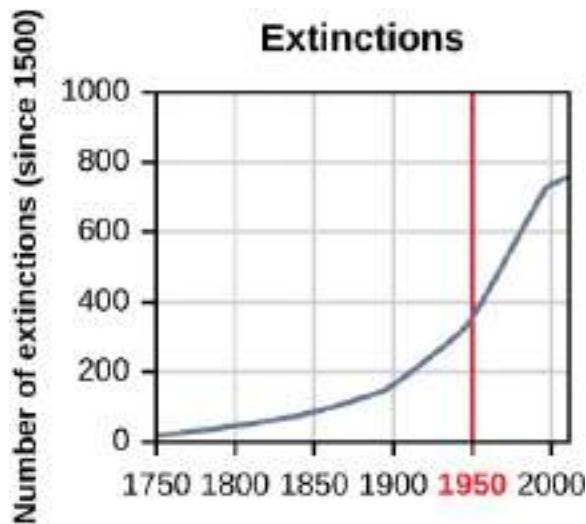

Historically, the Atlantic Ocean off Canada and the Northeast of the US has been some of the richest and most popular fishing grounds. Huge factory ships developed in the 1960's converged on the region from all over the world attracted by the rich catches. The graph shown represents the population of cod in recent years. Based on the graph, what is the likely explanation for the collapse of the northwest cod?

- a. A tropical disease decimated the populations of cod.
- b. Overfishing led to the collapse of the cod population.
- c. The cod population migrated somewhere else.
- d. The cod population is going through its cycle of rise and fall.

53.

The following graphs show the changes in the human population and the rate of extinction: Which statement most likely explains how the increase in human population could lead to a decrease in biodiversity?

- a. Every human added to the planet replaces a different species of organism.
- b. The more people inhabiting the planet, the more the average temperature increases, causing loss of other species.
- c. With the increase in population the demands for land, water, food, and energy increase, leading to the destruction of habitat.
- d. Increases in human population reduce the amount of land available for use by all species.

 tryptophan, 665  
 tryptophan (*trp*) operon, 640  
 tuber, 993  
 tubular reabsorption, 1419  
 tubular secretion, 1419  
 tumor suppressor gene, 435  
 Tumor suppressor genes, 428  
 tympanum, 1198

## U

ubiquinone, 297, 316  
 ulna, 1301  
 ultrasound, 1198  
 umami, 1198

unidirectional circulation, 1378  
unified cell theory, 150, 184  
uniporter, 215, 226  
unsaturated, 106  
unsaturated fatty acid, 131  
untranslated region, 665  
untranslated regions, 656  
up-regulation, 1242  
upstream, 600, 623  
urea cycle, 1419  
ureotelic, 1419  
ureter, 1419  
uric acid, 1419  
urinary bladder, 1419  
urine, 1419  
uterus, 1526

## V

vaccine, 876  
vacuole, 184  
vacuoles, 163  
vagina, 1526  
valence shell, 49, 78  
van der Waals interaction, 78  
van der Waals interactions, 57  
variable, 14, 36  
variable number of tandem repeats (VNTRs), 709  
variants, 486  
variation, 748  
vasa recta, 1419  
vascular bundle, 993  
vascular stele, 993  
vascular tissue, 993  
vasoconstriction, 1378  
vasodilation, 1378  
vasodilator, 1419  
vasopressin, 1419  
vein, 1379  
vena cava, 1379  
venation, 994  
venous  $P_{CO_2}$ , 1340  
venous  $P_{O_2}$ , 1340

ventilation/perfusion (V/Q) mismatch, 1340  
ventral cavity, 1047  
ventricle, 1152, 1379  
venule, 1379  
vertebral column, 1301  
vertical transmission, 876  
vesicle, 184  
Vesicles, 163  
vessel element, 994  
vestibular sense, 1198

vestigial structure, 748  
viable-but-non-culturable (VBNC) state, 924  
vicariance, 748  
villi, 1091  
viral receptor, 876  
virion, 876  
viroid, 876  
virus core, 876  
vision, 1198  
**vital capacity (VC)**, 1340  
vitamin, 1091  
viviparity, 1526

## W

water potential ( $\Psi_w$ ), 994  
wavelength, 339, 356  
Wax, 108  
wax, 131  
weather, 1576  
web of life, 837  
white blood cell, 1379  
white-nose syndrome, 1760  
Whole-genome sequencing, 698  
whole-genome sequencing, 709  
whorled, 994  
wild type, 486

## X

X inactivation, 530, 535  
X-linked, 489, 506

## Z

zero population growth, 1651  
zona pellucida, 1526  
Zoology, 33  
zoology, 36  
zoonosis, 924
